Differential Reinforcement of Low Rates of Responding (DRL)

Thomas Zane^{1,2} and Cheryl Davis³

Definition

Differential reinforcement of low rates of responding (DRL) is a procedure in which the implementer can lower the rate of a response by reinforcing fewer incidents of that response or by reinforcing longer time intervals between incidents of the response. For example, if an individual makes profanity statements an average of 20 times per half hour, an interventionist could provide a positive reinforcer contingent upon that individual making these statements 18 or fewer times per half hour.

A related term is differential reinforcement of diminishing rates (DRD). The technical difference between DRL and DRD is that in DRD, reinforcement follows a response that has been preceded by a minimum amount of time since the last response. DRL technically refers to providing reinforcement for fewer and fewer responses exhibited by the individual. However, DRL is the most common term and often refers to both of these procedures.

Historical Background

The three general areas of concern for persons with autism are social, behavior, and language. Many persons with this diagnosis display behaviors that are deemed inappropriate, such as aggression, self-stimulation, or self-injury that, if left untreated, can greatly interfere with the individual acquiring positive adaptive skills and becoming more independent. Psychologists and educators

have long investigated the best treatment for these types of concerns. One approach that has been studied extensively has been the use of restrictive or punitive procedures. These involve either presenting a stimulus that is aversive or unpleasant to the individual following the occurrence of the unwanted behavior or removing a desirable stimulus following the display of the unwanted behavior. Although these procedures have been shown to be effective in eliminating a wide variety of unwanted behaviors, they have been associated with a number of negative side effects, as well as potential ethical problems, including misuse and abuse.

Alternatives to punishment have been pursued vigorously in the research over the past few decades. One development has been that of functional assessment procedures, which allow the practitioner to determine the reinforcement maintaining the unwanted behaviors. Research has shown that if the reinforcement maintaining an unwanted behavior can be prevented from occurring, then the unwanted behavior will reduce in strength. Similarly, if an appropriate behavior that will earn the same reinforcement (function) as the unwanted behavior can be taught, then the individual will likely shift to the appropriate replacement behavior and reduce the occurrence of the unwanted behavior.

Along with functional assessment, researchers have developed a set of procedures that emphasize the use of positive reinforcement to reduce unwanted behaviors. Among these is the DRL procedure that focuses on reinforcing less occurrences of unwanted behavior and not reinforcing higher occurrences of unwanted behavior. The findings of dozens of studies show that using reinforcement in particular ways can have the same results as punishment in stopping targeted behaviors.

Current Knowledge

Even though the DRL procedure is used to reduce rates of a problem behavior, the reinforcement is delivered after the occurrence of that behavior,

which may seem counterintuitive. This is in contrast to the differential reinforcement alternative behavior (DRA), which reinforces appropriate replacement behaviors; differential reinforcement of incompatible behavior (DRI), which provides reinforcement for appropriate replacement behaviors that are physically incompatible with the targeted unwanted behaviors; or differential reinforcement of other behavior (DRO) procedure, in which the reinforcement is delivered in the absence of the target behavior. When using DRL, reinforcement occurs following an unwanted response that remains below a certain criterion or following an unwanted response that was preceded by progressively longer intervals of time from the previous response.

It is important to point out that the goal of a DRL procedure is to simply reduce the rate of the targeted behavior but not to eliminate it entirely. Some behaviors that might be considered undesirable at higher rates may be acceptably tolerated at lower rates, without needing to reduce them to zero. For example, perhaps it is acceptable for a child to get out of their seat in school a few times a week, but unacceptable and intolerable if it were to occur several times an hour. A child with autism who spontaneously verbalizes movie scripts only a few times per week could be considered more tolerable than engaging in this behavior several times per half-hour period. Thus, the DRL procedure is typically used when considering reducing behavior that is considered acceptable at lower rates but not at higher levels.

There are several variations of the basic DRL procedure. In “full session DRL,” the implementer provides reinforcement at the end of a session or a predetermined amount of time if the number of incidents of the undesired behavior falls at or below a predetermined criterion level. For example, a teacher divides the school day into 12 30-min sessions or time periods. Each half-hour consists of one “session.” A child engages in tantrums on an average of six per half-hour period. The initial rule for delivering reinforcement in this “full session DRL” program would be that the child engages in five or fewer tantrums in a session. As the rate drops to consistently five or

fewer, a new rule would be implemented, whereby reinforcement would be made contingent upon four or fewer occurrences in the session. Over time, by gradually reducing the criterion level, the DRL program will eventually bring the rate of behavior to an acceptable level. Note also that in full session DRL, the individual has an opportunity to earn reinforcement numerous times, across the multiple sessions, since each new session signals a new opportunity.

Another type of DRL is the “interval DRL,” which is a procedure for implementing DRL in which the total session is divided into equal intervals and reinforcement is provided at the end of each interval in which the number of responses during the interval is equal to or below a criterion limit. Similar to the full session DRL, this would involve taking the full session and breaking it down into smaller intervals and reinforcement could be delivered during each of those intervals. For example, a teacher divides a 30-min lunch period into three 10-min intervals. A child is out of his or her seat on an average of 21 times during the lunch period. The rule for delivering reinforcement in this “interval DRL” would be that if the child was out of seat six or fewer times in each 10-min period, reinforcement would be provided. A potential advantage of an interval DRL program is that the individual has multiple opportunities within a session to earn reinforcement, as opposed to just one opportunity (at the end of the session).

A third variation of the basic DRL procedure is the “space-responding DRL” (sometimes called DRD). This is a procedure for implementing DRL in which reinforcement follows each occurrence of the target behavior that is separated from the previous response by a minimum inter-response time (IRT). For example, a child correctly answers questions asked by the teacher but answers so quickly that other students have no opportunity to be called on. The teacher makes a rule with this student that to be called on to answer a question, 3 min must have elapsed since the child last answered a question. Thus, the rule for reinforcement is that only responses that have been preceded by a minimum of 3 min from the previous response will receive reinforcement.

The basic procedural components of all DRL procedures are these. First, the interventionist must operationally define the targeted unwanted behavior to be changed. This must be done to allow for both correct recording of its occurrence (so the interventionist can objectively determine if the differential reinforcement procedure is having the desired weakening effect) and accurate implementation of the procedure (i.e., so that the interventionist(s) implement the DRL plan consistently).

The second step in using DRL is to determine the current “operant level” of the response. That is, the interventionist must have data showing the current rate of the behavior before implementing DRL. Depending upon the type of DRL procedure used, data might show the total number of responses during a day, the total number of responses (on average) during individual sessions, and/or the average amount of time between occurrences of the targeted undesired behavior.

The third step in using DRL procedures is to determine the actual reinforcement that will be made contingent upon the response meeting the rule for earning reinforcement. This, by necessity, will vary across individuals due to the fact that what constitutes a motivating reinforcer is personalized. However, most of the time, the interventionist will use some form of positive reinforcement, such as praise, smiles, tokens, or other forms of tangible reinforcement desired by the learner. On occasion, the interventionist might use a form of negative reinforcement, such as allowing the individual to escape a work demand contingent upon displaying the targeted response. For example, in the case where a person tantrums in order to escape or avoid work, the caregiver might allow the individual to take a break from work if she/he asks for a break instead of tantruming. In this procedure, asking for a break is negatively reinforced by allowing the individual to briefly escape an unpleasant work demand. However, if the person continues to tantrum and does not ask appropriately for a break, the caregiver would continue to keep the individual in the demand situation and constantly require work. The use of formal reinforcement preference

assessments is considered a best practice to determine the most motivating reward items available.

The last step in the procedure is to determine the actual rule for providing reinforcement. Three rules or criteria must be planned. First, the rule for what level of behavior will be required as the initial new criterion must be established. To determine this, the interventionist would set the initial criterion at or a little below the operant level. For example, if the operant level was ten occurrences per session or interval, the initial DRL criterion would be anywhere from eight to ten. The second rule that must be determined is the criterion for changing from the current criterion to a new, lower one. This criterion would specify the number of sessions that must be at the criterion level before changing to a new one. For example, the interventionist may decide that if the criterion was met, or below, for three consecutive sessions, the next lower criterion would be implemented. The final rule that must be established is the ultimate, terminal criterion at which point the interventionist would consider an acceptable level of the behavior and at which point the DRL plan would be discontinued. For example, if the operant level was ten per session, the interventionist may set two per session as the ultimate criterion to discontinue the DRL.

An excellent example of DRL that has been shown to be effective is called the "Good Behavior Game." This procedure involves dividing a group of individuals (such as students in a classroom) into two or more teams. The goal is to be the team with the fewest occurrences of undesired behaviors. Generally, the interventionist would periodically observe each team and note whether or not undesired behaviors are occurring. After a set period of time (e.g., end of the day, before lunch, etc.), the team with the fewest occurrences of the targeted undesired behavior will earn some type of positive reinforcer.

DRL is a positive procedure in that it utilizes only reinforcement to reduce undesired behaviors. It is also advantageous in that it is more easily tolerated than a behavior-reduction procedure that only provides reinforcement for the *absence* of the targeted behavior (i.e., DRO). The goal of DRO is the cessation of the unwanted behavior.

A complete elimination would generally be considered more difficult to achieve than allowing some (but lower) level of the target behavior. The individual exhibiting the target behavior may more easily tolerate being allowed some amount of unwanted behavior, than attempting to eliminate it altogether. That is why DRL is often successful; it results in a targeted behavior that is inappropriate at higher levels becoming appropriate and tolerated at lower levels. Lastly, DRL procedures have been shown in the literature to be effective procedures with a wide variety of individuals and target problems; thus, it has good generalization evidence.

There are several considerations for using DRL most effectively. Firstly, the interventionist must recognize that the DRL procedure does not produce rapid behavior change; rather, it produces slow and gradual changes. So, one must use DRL to change behaviors that are amenable to gradual change. Secondly, practitioners should not use DRL when targeting behaviors that could be physically harmful to the individual or others (such as self-injury, aggression, etc.). For those categories of behaviors, the interventionist should use procedures that have more of an immediate impact or combine DRL with such strategies. Lastly, DRL does, by its nature, focus on the undesired behavior, rather than reinforcing appropriate replacement behaviors. This suggests that the implementer combines DRL with procedures that target and reinforce appropriate replacement behaviors.

Future Directions

When developing programs for children with autism, often part of that programming focuses on attempting to reduce problem behaviors. The set of DRL programs could be useful in that regard, depending upon the characteristics of the undesired behavior. Future directions could include clarifying the specific behavioral or contextual variables that would suggest a particular DRL program be used over another type of program, such as DRA, DRI, DRO, or more restrictive techniques. In addition, rules for determining

the combination of DRL with other programs to specifically teach, model, and reinforce appropriate incompatible behaviors (to the undesired ones) would be useful for practitioners.

Differential Reinforcement Procedures of Alternative Behavior (DRA/DRAIt) of Incompatible Behavior (DRI)

Thomas Zane

Van Loan School of Graduate and Professional Studies, Endicott College, The Institute for Behavioral Studies, Beverly, MA, USA
Department of Applied Behavior Science, University of Kansas, Lawrence, KS, USA

Definition

Differential reinforcement of alternative behaviors (DRA) and differential reinforcement of incompatible behaviors (DRI) are both procedures designed to decrease the rate of targeted unwanted behaviors. Targeted behaviors decrease due to two mechanisms – reinforcement of appropriate behaviors that will replace the unwanted behavior and the withholding of reinforcement that historically followed the unwanted behavior. DRI is often considered a type of DRA procedure.

With both of these procedures, reinforcement is contingent upon specific behaviors that will replace the unwanted behavior. The nature of the replacement behaviors marks the difference between DRA and DRI. In DRI, the replacement behaviors are physically incompatible with the unwanted behavior. They both cannot be done at the same time. For example, if the unwanted behavior were out of seat, a physically incompatible behavior would be staying in seat. If the unwanted behavior were putting fingers in the mouth, a physically incompatible behavior would be putting hands in pants pockets. Thus, with a DRI procedure, the replacement behavior is both an appropriate one, as well as physically incompatible with the unwanted behavior. In DRA, there is no concern about the replacement behaviors being physically incompatible; it is simply an appropriate behavior that could fulfill the same function as the unwanted behavior. For example, if the unwanted behavior were screaming (to indicate a need to escape a work demand),

an interventionist might use a DRA procedure and select an appropriate replacement behavior such as pointing to a card to signal a need to break from work. Another example would be that if the unwanted behavior were a child inappropriately calling out answers in class (without waiting for the teacher to call on her), an appropriate replacement behavior would be to raise her hand to be called on. Note that in both of these examples, the appropriate replacement behavior is *not* physically incompatible with the targeted unwanted behavior; both the unwanted behavior and the replacement behavior could be displayed simultaneously. In both procedures, reinforcement is delivered for the alternative or incompatible behavior, and reinforcement is withheld (extinguished) from the targeted unwanted behavior. Both procedures result in a decrease in rate of the unwanted behavior. The strength of these procedures lies in the discrimination between the two – the alternative or incompatible behaviors are reinforced, while the unwanted behaviors are not.

Historical Background

The three general areas of concern for persons with autism are social, behavior, and language. Many persons with this diagnosis display behaviors that are deemed inappropriate, such as aggression, self-stimulation, or self-injury and that greatly interfere with the person learning positive adaptive skills and increasing their independence in life. Psychologists and educators have long investigated the best treatment for these types of concerns. One approach that has been studied extensively has been the use of restrictive or punitive procedures. These involve either presenting a stimulus that is aversive or unpleasant to the individual following the occurrence of the unwanted behavior or by removing a desirable stimulus following the display of the unwanted behavior. Although these procedures have been shown to be effective in eliminating a wide variety of unwanted behaviors, they have been associated with a number of negative side effects, as well as

potential ethical problems, including misuse and abuse.

Alternatives to punishment have been pursued vigorously in the research over the past few decades. One development has been that of functional assessment procedures, which allow the practitioner to determine the reinforcement maintaining the unwanted behaviors. Research has shown that if the reinforcement maintaining an unwanted behavior can be prevented from occurring, then the unwanted behavior will reduce in strength. Similarly, if an appropriate behavior that will earn the same reinforcement (function) as the unwanted behavior can be taught, then the individual will likely shift to the appropriate replacement behavior and reduce the occurrence of the unwanted behavior.

Along with functional assessment, researchers have developed a set of procedures that emphasize the use of positive reinforcement to reduce unwanted behaviors. Among these are the DRA and DRI procedures that focus on simultaneously reinforcing behaviors that can replace the unwanted behavior and removing the reinforcement that has maintained the targeted unwanted behavior. Findings of dozens of studies show that using reinforcement in particular ways can have the same results as punishment in stopping targeted behaviors.

Current Knowledge

Differential reinforcement procedures have been found to be some of the most frequently used procedures to reduce and eliminate unwanted behaviors, across educational, social, and vocational contexts. DRA is useful for behaviors that may occur at high or low rates, as this procedure involves teaching the individual to engage in a more appropriate behavior than the behavior targeted for reduction. Often, DRA is combined with DRI. DRI is preferable, as the student cannot engage in the targeted behavior for reduction since the reinforced response is physically incompatible with the unwanted behavior.

The procedural steps for both DRA and DRI are similar. First, the implementer must

operationally define the targeted unwanted behavior to be reduced or eliminated so that the implementer(s) will not deliver reinforcement after its occurrence and that there will be increased accuracy in data collection, to confirm (or not) if the differential reinforcement procedure is having the desired effect. With both of these procedures, the implementer must track the occurrence of both the targeted unwanted behaviors, as well as the alternative and incompatible ones.

Second, the interventionist should determine the function of the unwanted behavior. This information is helpful when deciding the procedures to use to prevent the reinforcement of the unwanted behavior (see below), as well as in guiding the selection of the appropriate replacement behaviors, which is the third step. The implementer must operationally define one or more behaviors that will be (a) desirable alternatives to the unwanted behaviors, (b) fulfill the same function as the unwanted behaviors, and (c) preferably be physically incompatible or compete with the unwanted behaviors. For example, if the unwanted behavior is swearing when frustrated, then an alternative behavior to strengthen could be having the individual write down what is frustrating. When planning on using a DRI procedure, the implementer must define an appropriate behavior that is physically incompatible with the targeted inappropriate one. In the example of an individual swearing, an incompatible behavior to reinforce could be saying, "oh, I am so frustrated, I need help!" instead of swearing. Note that expressing frustrating using that phrase is physically incompatible with swearing.

The fourth step in using DRA or DRI is to determine the actual reinforcement that will be made contingent upon the required alternative or incompatible response. The implementer will be guided by two considerations here – the function of the unwanted behavior (determined through a functional assessment) and the preferences of the individual. Reinforcement needs to be determined based upon the particular individual with whom the implementer is working, since reinforcement is so individualized. Most of the time, the implementer will use some form of positive reinforcement, such as praise, smiles, good grades, tokens,

or other forms of tangible reinforcement desired by the person. On occasion, the implementer might use a form of negative reinforcement, such as allowing the individual to escape a work demand contingent upon displaying the targeted response. These procedures are referred to as differential negative reinforcement of alternative behaviors (DNRA) and differential negative reinforcement of incompatible behaviors (DNRI). For example, in the case where a person tantrums in order to escape or avoid work, the caregiver might allow the individual to take a break from work if she/he asks for a break instead of tantruming. Thus, in this procedure, asking for a break is negatively reinforced by allowing the person to briefly escape an unpleasant work demand. However, if the individual continues to tantrum and does not ask appropriately for a break, the caregiver would keep the individual in the demand situation and continue to present work demands. The use of formal reinforcement preference assessments is considered best practice to determine the most motivating reward items available.

The last step in the procedure is to identify the extinction procedures to implement contingent upon the occurrence of the targeted unwanted behavior. The results of the functional assessment are critically important here. Once the reinforcement for the unwanted behavior has been determined, the interventionist must plan on how to prevent that reinforcement from occurring when the unwanted behavior is emitted. In the case of using DRA and DRI, the implementer will need to ensure that no reinforcement follows the unwanted behavior. For example, when an individual swears, how will the implementer react? In DRA and DRI, the implementer must ignore the swearing and not comment or react to it and focus on reinforcing the occurrence of the alternative or incompatible behavior.

There are several advantages to DRA procedures. Of particular importance is the focus on appropriate behavior. These procedures require specification of appropriate and positive behaviors to strengthen in the individual, which will contribute to the individuals' overall level of reinforcement. They learn what to do, not just what *not* to do. A second advantage of this group of

procedures is that they are associated with few or no negative side effects, unlike more restrictive procedures, such as time-out, overcorrection, and other forms of punishment. Since DRA/DRI is associated with reinforcement for appropriate responding, the individual receiving the reinforcement will likely show positive affect, demonstrate generalized responding, and develop a positive relationship with the interventionist.

A third and equally important advantage is that practitioners view these procedures quite positively, much more so than punitive or restrictive ones. Caregivers, thus, are more likely to carry out these procedures with greater willingness and fidelity. A final advantage is that DRA procedures are associated with long-term positive change. As the unwanted behavior decreases in strength, and the appropriate behaviors increase, there should be continued suppression and elimination of the unwanted behavior.

When considering the use of this group of procedures, it has been shown that the effect on the targeted replacement behavior may take some time. Reinforcement does result in behavior change, but the change may not be that rapid. To increase the speed of behavior change, it is recommended selecting powerful reinforcers. Another way to further increase the speed of further progress, one should select alternative or incompatible behaviors that already exist in the individual's repertoire. These appropriate behaviors should already be occurring at some level so that the implementer has opportunities to reinforce them when they occur. Although interventionists could teach a new skill or behavior as the replacement behavior, this simply complicates the effort involved. As with most behaviors that are targeted for increase, it would be important to select these appropriate behaviors that will likely be naturally reinforced in the individual's daily environment. It is also good practice to select these alternative and incompatible behaviors that will be less effort to emit than the targeted unwanted one. As noted earlier, of equal importance is to select replacement behaviors that are incompatible with the unwanted behavior.

In addition, there is a potential danger of a DRA procedure that focuses on a limited group

of replacement behaviors of reducing the strength of other, equally appropriate replacement behaviors. For example, consider an unwanted behavior of screaming to escape or avoid a work situation. If the interventionist selected one appropriate replacement behavior, that of pointing to a break card, the individual may learn to use that card when a break is desired but at the same time, no longer asks for a break using words or a communication device. To avoid this potential result, the interventionist should select all replacement behaviors that could serve the same function as the targeted unwanted behavior.

Lastly, the implementer must *consistently* reinforce the alternative and incompatible behaviors and *consistently* extinguish the unwanted behavior. The procedures are less effective when some instances of the alternative or incompatible behaviors are not reinforced and some instances of the unwanted behavior continue to achieve reinforcement. Extinction of the unwanted behavior seems to be important in the success of DRA/DRI. Research has shown that these procedures will be less effective if the unwanted behavior continues to result in reinforcement.

Future Directions

Differential reinforcement of alternative/incompatible behaviors should be seriously considered when planning on addressing unwanted behaviors. To use these procedures effectively, the practitioner must carefully determine the reinforcement for the unwanted behavior, plan powerful reinforcement to strengthen the appropriate behavior, and develop procedures for preventing the unwanted behavior from being rewarded. When working with individuals who display unwanted behaviors in which it may be difficult to prevent the reinforcement for those behaviors, caregivers will need to determine how to manipulate the reinforcement for the replacement behaviors in a way to promote their increase, regardless of the reinforcement for the unwanted behaviors. For example, the use of intermittent

reinforcement, increased duration of reinforcement, or a greater magnitude of reinforcement for the appropriate replacement behaviors could be considered.

Differential Reinforcement Procedures of Other Behavior (DRO)

Thomas Zane^{1,2} and Cheryl Davis³

¹Van Loan School of Graduate and Professional Studies, Endicott College, The Institute for Behavioral Studies, Beverly, MA, USA

²Department of Applied Behavior Science, University of Kansas, Lawrence, KS, USA

³7 Dimensions Consulting, Worcester, MA, USA

Definition

Differential reinforcement of other behaviors (DRO) is a reinforcement procedure in which reinforcement is delivered for any response *other than* a specific target behavior. This procedure results in a decrease in that specific target behavior because that behavior is never followed by reinforcement; thus, it weakens in future rate. For example, if a child with autism displays self-stimulatory behavior in the form of waving both hands in front of his face, a DRO procedure would be to provide a positive reinforcement for a 10-s period during which his hands were *not* waving in front of his face. Other names for this procedure include differential reinforcement of zero occurrences or omission training.

Historical Background

When considering interventions for undesirable behaviors, interventionists initially found punishment procedures to be effective. Although such procedures as overcorrection, time-out, and response cost do indeed reduce unwanted behavior, there are often negative side effects for the individual being exposed to those procedures, and historically, there have been abuses using aversive techniques. As more research was conducted on dealing with unwanted behaviors, professionals learned that using positive procedures could be an effective tool in obtaining reductions in these

behaviors. Generally speaking, differential reinforcement has been shown to both increase appropriate behaviors and reduce the strength of unwanted responses. One form of differential reinforcement that has been shown in the research to be quite effective in weakening problem behaviors is DRO. This technique has been shown to be effective across a wide variety of unwanted behaviors exhibited by a variety of individuals.

Current Knowledge

Differential reinforcement of other behaviors (DRO) is a procedure for decreasing problem behavior in which reinforcement is contingent on the absence of the problem behavior during or at specific times. DRO is perhaps the simplest of all behavior reduction procedures as it involves the simple rule of providing reinforcement whenever the specific undesirable behavior is *not* displayed. DRO differs from differential reinforcement of alternative behaviors (DRA) and differential reinforcement of incompatible behaviors (DRI) in that with those two procedures, reinforcement follows specific appropriate responses. In DRO, reinforcement is provided contingent upon passage of time in which the targeted undesired behavior does not occur. Note that reinforcement does not follow any specific response; it can follow any response as long as that response is not the targeted undesirable behavior. Because the “other” behaviors are not defined, no one behavior is reinforced so much that it is likely to increase in strength. But what does happen is that the targeted undesirable behavior is never reinforced, so over time, it reduces in rate.

There are basically two types of DRO, whole-interval and momentary-interval. The whole-interval DRO is a procedure in which reinforcement is available at the end of a fixed interval of duration if the targeted unwanted behavior did not occur at any time throughout that interval. For example, a child with autism is often out of her seat during independent work time. A whole-interval DRO procedure could involve dividing the independent work time period into six 5-min

periods. During each 5-min period, the teacher observes the child, and if the child does not get out of seat at all during a 5-min period, the teacher delivers reinforcement. However, if the child did get out of seat during a 5-min period, no reinforcement will be provided; the child will have another opportunity at the beginning of the next 5-min interval. Since the out-of-seat behavior is not reinforced by the teacher, and other behaviors are, the out-of-seat behavior should begin to diminish in rate. This procedure requires constant vigilance and observation on the part of the interventionist throughout the interval, so as to observe any occurrence of the target behavior. This DRO is appropriate for high or low rates of challenging behaviors, as the interval can be set according to the rates of challenging behaviors. Typically, one sets the interval just below the pre-intervention IRT duration of the problem behavior (see below).

The momentary DRO is a procedure whereby reinforcement is available at specific moments of time and delivered contingent on the problem behavior not occurring at that those precise moments. For example, a child with autism often whines while playing at home. A caregiver could make a rule that every 2 min (and exactly at the 2-min mark), the child will be provided a reinforcer if, *at that very moment of observation*, there is no whining being emitted. Thus, reinforcement is delivered at the moment of observation if the individual is doing anything other than whining. Note that this DRO procedure does not demand constant vigilance and attention on the part of the interventionist as does the whole-interval DRO. Using a momentary DRO allows the interventionist to be attentive to the individual only at the precise moment specified by the DRO schedule. Whether reinforcement is delivered is not dependent upon whether the targeted behavior was present or absent before or after the moment of observation; reinforcement is entirely dependent upon whether it is occurring at the precise observational moment.

There are two variations of the whole- and momentary-interval DRO procedures. The intervals can be a fixed or variable duration. Thus, a fixed-whole-interval DRO consists of the interval size being standard across all intervals. However,

a variable-whole-interval DRO consists of the interval duration varying per interval. For example, the intervals could range from 5, 10, 35, 3, and so forth but varying around a set mean. Momentary-interval DRO programs can be either fixed or variable. A fixed-momentary-interval DRO consists of the interval size being standard across all intervals; a variable-momentary-interval DRO plan allows each interval to vary around some average duration. The advantage of the variable DRO is that individuals cannot predict when the interval will end and reinforcement is available. All DRO procedures target the reduction of targeted inappropriate behavior. The research on which DRO procedure to use shows mixed results; both types of DRO plans can be effective in reducing the targeted undesired behavior.

The basic procedural components of all DRO procedures are these. First, the interventionist must operationally define the target behavior to be changed. That requires carefully specifying the targeted unwanted behavior to allow for both correct recording of its occurrence (so the interventionist can objectively determine if the differential reinforcement procedure is having the desired weakening effect) and accurate implementation of the procedure (i.e., so that the interventionist (s) know exactly when reinforcement should or should not be provided). The second step in using DRO is to determine the actual reinforcement that will be made contingent upon the absence of the unwanted response and how it will be delivered. This, by necessity, will vary across individuals due to the fact that what constitutes a motivating reinforcer is so personalized. However, most of the time, the interventionist will use some form of positive reinforcement, such as praise, smiles, tokens, or other forms of tangible reinforcement desired by the learner. On occasion, the interventionist might use a form of negative reinforcement, (termed differential negative reinforcement of other behavior, or DNRO) such as allowing the learner to escape a work demand contingent upon displaying the targeted response. For example, in the case where an individual tantrums in order to escape or avoid work, the caregiver might allow the person to take a break from work if she/he asks

for a break instead of tantruming. In this procedure, asking for a break is negatively reinforced by allowing the person to briefly escape an unpleasant work demand. However, if the individual continues to tantrum and does not ask appropriately for a break, the caregiver would continue to keep the person in the demand situation and constantly require work. The use of formal reinforcement preference assessments is considered best practice to determine the most motivating reward items available.

The third step in implementing a DRO procedure is to determine which type of DRO will be used, interval or momentary, and the criteria for establishing the initial interval size and increasing the interval size as the behavior begins to weaken. Once the type of DRO program is decided, the interventionist must determine the interval size to use to begin the procedure. Research has shown the most success is seen when the initial interval size is set small and gradually lengthened over time, as the targeted behavior reduces in rate. This should be based upon pre-intervention levels of the problem behavior and the average inter-response time (IRT) duration historically observed. The formula for calculating IRT is to divide the total number of responses observed during a certain time interval by the total amount of time of that interval. For example, if during pre-intervention conditions, the individual exhibits the target behavior, on average, ten times every hour, the mean interval between occurrences is 6 min (ten occurrences of the behavior divided by 60 min). That information can then be used to establish the initial interval size for the DRO procedure. Next, the interventionist must develop a criterion for increasing the interval duration as the DRO program demonstrates success. For example, if the practitioner begins with an interval size of 6 min and over 90% of the intervals shows no targeted problem behavior over 3 consecutive days, then the interval size could be increased to 7 min. Such a mastery criterion if developed, in advance, will result in both increased progress in decreasing the problem behavior and a procedure gradually easier to implement.

The last step in the procedure is to determine exactly how to respond to the display of the

targeted undesired behavior. The rule in DRO is to not provide any reinforcement (regardless of function) for its occurrence. So, the interventionist must be careful not to react in any way that could possibly provide any source of reinforcement for its occurrence. An important question is whether the inappropriate behavior can be ignored or if it is such a serious behavior that some sort of intervention must apply. In the case of shouting out an answer, it is probably the case that ignoring it can be done effectively. However, in other situations, with other behaviors such as self-injury or aggression, not reacting may be difficult, due to potential safety issues. In those cases, DRO may not be the method of choice.

There are several advantages to DRO such as the procedure is positive, is easy to implement, and focuses solely on the use of reinforcement to decrease undesired behaviors. Reinforcers are not removed from the individual, and few to no negative side effects are reported. Interventionists appreciate and are more willing to use positive procedures as opposed to more aversive or unpleasant interventions. Since these procedures are generally effective and positive, they are more ethically appropriate as a treatment choice. DRO is easy for teachers to use in most classrooms and school settings and has been shown to work across a wide variety of populations and contexts. The effect of such procedures is more rapid than simply extinguishing the targeted undesired behavior; although extinction can work, the application of DRO produces quicker change. Additionally, the effects of DRO have been shown to be long-lasting, producing durable response suppression. A particular advantage of a momentary DRO is that it does not require such continuous attention, and for a busy teacher or parent, that can be a useful feature. With this procedure, at the moment of observation, the interventionist can interrupt what she/he is doing, observe whether or not the targeted undesirable behavior is occurring, and deliver (or not deliver) the reinforcement based upon that immediate observation.

However, there are several potential disadvantages to DRO procedures. One is that such

procedures are not designed to teach and/or increase any particular appropriate behavior. Its inherent characteristic is to focus on the *absence* of the targeted behavior, and there is no attempt to operationally define and strengthen an appropriate replacement behavior. Another potential limitation of this procedure is that it focuses the attention of the interventionist on the negative or undesired behavior. Since its occurrence triggers whether or not reinforcement is delivered, the interventionist is paying attention primarily to whether or not the problem behavior occurs. This may result in the individual inadvertently getting attention for the problem behavior. Thus, caregivers need to be aware of any potential reaction being given to the individual following the occurrence of the targeted unwanted behavior. Another potential disadvantage of the DRO procedures is that since reinforcement is delivered for any response *other than* the targeted undesired behavior, there is a risk that other behaviors equally undesirable may inadvertently be reinforced and thus strengthened. For example, consider a DRO procedure used to reduce the self-stimulatory behavior of jumping up and down repeatedly. With DRO, reinforcement is given whenever jumping is not occurring. However, if the individual is not jumping but instead waving fingers in front of the face, reinforcement would be allowed (since the rule is to provide reinforcement for any response other than jumping). This potential disadvantage is possible when working with an individual who displays a large number of undesired behaviors. If this potential exists, a recommendation would be to provide the reinforcement only when none of the undesired behaviors are occurring or to use a procedure other than DRO (such as DRA or DRI).

Future Directions

DRO procedures are effective, show long-lasting results, are relatively easy to implement, and are preferred by interventionists due to their positive nature. Further clarification of the behavioral

characteristics of when to use which type of DRO would enhance its use and effectiveness. Guidelines for establishing initial interval size and criterion for increasing the interval duration would be helpful as well.

Diffusion Tensor Magnetic Resonance Imaging

Roger J. Jou¹ and Lawrence H. Staib²

²Department of Diagnostic Radiology, Yale University School of Medicine, New Haven, CT, USA

Definition

Diffusion tensor imaging (DTI) is a magnetic resonance imaging (MRI) modality used in brain imaging which measures characteristics of water diffusion in vivo to make inferences on the underlying neuroanatomy, such as the structural integrity of white matter. White matter structures probed include major neuronal fiber tracts such as association (e.g., superior longitudinal fasciculus), commissure (e.g., corpus callosum), and projection (e.g., corticospinal tract) fibers. Water diffusion can be characterized at each anatomical location by the diffusion tensor, a second-order model which provides the direction and the degree of anisotropy (i.e., directionality). The diffusion tensor can be visualized as an ellipsoid and generally aligns with the underlying white matter fibers. Diffusion properties in tissue can then be captured using various numeric metrics computed from the tensor and commonly include fractional anisotropy (FA), radial diffusivity (RD), axial diffusivity (AD), mean diffusivity (MD), and apparent diffusion coefficient (ADC), with FA being the most widely utilized in neuropsychiatric research.

There are some general relationships between the aforementioned metrics and biological features of tissue. Thus, knowledge of these inferences can guide the interpretation of research findings using DTI. Each of these measures aims to characterize the restriction of water diffusion due to physical barriers such as membranes and myelin; therefore, they are used as surrogates for white matter structural integrity in DTI studies.

RD is a measure of the inhibited water diffusion occurring across or perpendicular to nerve fibers. Causes of increased restriction perpendicular to the fiber (a low RD) include thicker myelin, a more water-impermeable myelin, denser packing of fibers, and/or smaller fiber diameters. Less restriction (a high RD) could be due to delayed myelination, loss of myelin, more water-permeable myelin, loss of axonal membrane integrity, looser fiber packing, disorganized fiber packing, and/or larger-diameter fibers. On the other hand, AD is a measure of water diffusion occurring along or parallel to nerve fibers. A higher AD value indicates less hindrance to water movement along axons and could be due to axonal loss and/or less-dense fiber packing. MD and ADC measure average water diffusion in all directions. Finally, FA ranges from zero to one and describes the degree to which water diffusion is directionally dependent. A value of zero means that water diffusion is isotropic; it is equally restricted in all directions such that the pattern of diffusion resembles a sphere. A value of one means that water diffusion is completely restricted to a single direction. FA is most frequently used to characterize white matter integrity. Regardless of the specific measure, however, each of these parameters provides different information about the underlying white matter architecture. Because of this, considering multiple measures has become a common approach in DTI studies.

Moreover, DTI can also be used to reconstruct the 3D structure of white matter fiber tracts using a technique called tractography or “fiber tracking.” Algorithms are used to determine 3D curves which trace fibers by following the orientation of maximum water diffusion. These fibers can then be visualized resulting in spectacular images of multiple fiber pathways. Tractography is now being used regularly in the study of neuropsychiatric disorders such as autism. Previously, such white matter anatomy could only be studied by postmortem dissection or invasive tracing studies in nonhuman animals. Because of this, tractography has been referred to as “virtual dissection.”

DTI has revolutionized the study of structural brain connectivity in humans and is extensively

used in the field of autism research to study alterations in neural connectivity. In the past 5 years, there has been a surge in the number of DTI studies published in autism research with the overall consensus being that some level of impairment exists in structural brain connectivity likely in the direction of underconnectivity. The focus of this chapter is the application of DTI in the study of the neurobiology of autism spectrum disorders (ASD). While a brief description of the technical aspects of DTI has been provided, the reader is referred to other reading which covers the technical details of DTI in much greater detail (Mori 2007; Mori and Zhang 2006).

Historical Background

Interestingly, diffusion MRI had been known for many decades as a source of obtaining tissue contrast. Early work in the 1950s by Hahn (1950), Carr and Purcell (1954), and Torrey (1956) laid the groundwork for diffusion measurements from magnetic resonance, providing an understanding of the change in the magnetic resonance signal in the presence of water diffusion. Stejskal and Tanner (1965) advanced this formulation and incorporated the diffusion tensor. Finally, Basser and colleagues (1994) developed the acquisition strategy that allowed computation of the diffusion tensor. Using multiple acquisitions, each sensitive to diffusion in a specified direction, the diffusion tensor can be reconstructed at each location in the brain image.

Current Knowledge

At the time of this writing, there are over 30 studies using diffusion imaging, investigating the neurobiology of ASD since the first study was published in 2004 (Barnea-Goraly et al. 2004). In recent years, the number of studies has increased sharply: one study in 2004, five studies in 2007, eight studies in 2009, and 13 studies in 2010 (all reviewed below). The methods implemented in these studies are diverse, ranging from voxel-wise comparisons to tractography-based studies. Some studies use a combination

of methods or other MRI modalities such as structural and/or functional MRI. The DTI studies reviewed in this chapter are presented according to their methodology which will include voxel-wise, region of interest (ROI), tractography, combination DTI, and multimodal MRI studies. White matter properties vary with age through development. Thus, in order to better appreciate the developmental aspects of ASD, these DTI studies are further subdivided into child (age <13 years), adolescent (13–20 years), and adult (age $\geq$ 21 years) categories based mainly on the average age of ASD participants.

Voxel-Wise

The first DTI study published in the autism research literature was a voxel-wise study. Thus, it comes as no surprise that voxel-wise studies are the most common of the DTI studies in ASD. In general, image volumes are warped to a common space, and then, groups are compared on a voxel-by-voxel basis within the white matter. A variety of statistical procedures are used to identify significant differences and control for false positives which can result from the large numbers of comparisons made (each brain contains thousands of voxels). At the time of this writing, there are 10 DTI studies which utilize a voxel-wise approach in the study of ASD. Overall, these studies demonstrate diffuse abnormalities in white matter using the previously mentioned metrics, though the most commonly reported abnormality is a reduction in FA.

There are four studies which implement a voxel-wise analysis studying children with ASD. Cheung and colleagues (2009) reported on a comparison of 13 children with autism (9.3 ± 2.6 years) and 14 controls (9.9 ± 2.5 years) where FA in the autism group was significantly lower than controls in bilateral prefrontal and temporal regions, particularly in the right ventral temporal lobe adjacent to the fusiform gyrus. Additionally, FA was greater in the right inferior frontal gyrus and left occipital lobe. Barnea-Goraly and colleagues (2010) reported on a comparison of 13 children with autism (10.5 ± 2.0 years), 13 of their unaffected siblings (8.9 ± 1.9 years), and 11 controls (9.6 ± 2.1 years). Both the autism and unaffected sibling groups had widespread

FA reductions in the frontal, parietal, and temporal lobes, including regions known to be important for social cognition. Within regions of reduced FA, reductions in AD with preserved RD were observed. There were no differences in white matter structure between autism and unaffected sibling groups. Sahyoun and colleagues (2010a) reported on a comparison of nine children with autism (12.8 ± 1.5 years) and 12 controls (13.3 ± 2.45 years). Controls showed increased FA within frontal white matter and the superior longitudinal fasciculus. The autism group showed increased FA within peripheral white matter, including the ventral temporal lobe. Shukla and colleagues (2011) reported on a comparison of 26 children with ASD (12.8 ± 0.6 years) and 24 controls (13.0 ± 0.6 years). The ASD group demonstrated decreased FA and increased MD and RD in numerous white matter structures: corpus callosum, anterior and posterior limbs of the internal capsule, inferior longitudinal fasciculus, inferior fronto-occipital fasciculus, superior longitudinal fasciculus, cingulum, anterior thalamic radiation, and corticospinal tract. There were no areas of increased FA, reduced MD, or RD in the ASD group.

There are four studies which implement a voxel-wise analysis studying adolescents with ASD. In the first published DTI study in ASD, Barnea-Goraly and colleagues (2004) reported on a comparison of seven adolescents with autism (14.6 ± 3.4 years) and nine controls (13.4 ± 2.8 years). The autism group demonstrated reduced FA in white matter adjacent to the ventromedial prefrontal cortices, anterior cingulate gyri, and temporoparietal junctions. FA reductions were also seen adjacent to the superior temporal sulcus bilaterally, temporal lobes approaching the amygdala bilaterally, occipitotemporal tracts, and corpus callosum. Cheng and colleagues (2010) compared 25 adolescents with ASD (13.71 ± 2.54 years) and 25 controls (13.51 ± 2.20 years), reporting reduced FA in the right posterior limb of internal capsule with increased RD distally and reduced AD centrally. ASD adolescents also demonstrated greater FA with reduced RD in the frontal lobe, greater FA with reduced RD in the right cingulate gyrus, greater FA with reduced RA with increased AD

in the bilateral insula, greater FA with reduced RD in the right superior temporal gyrus, and greater FA with reduced RD in the bilateral middle cerebellar peduncle. Noriuchi and colleagues (2010) reported on a comparison of seven adolescents with ASD (13.96 ± 2.68 years) and seven controls (13.36 ± 2.74 years). For the ASD group, FA and AD were lower in the white matter around left dorsolateral prefrontal cortex, posterior superior temporal sulcus/temporoparietal junction, right temporal pole, amygdala, superior longitudinal fasciculus, occipitofrontal fasciculus, mid- and left anterior corpus callosum, and mid- and right anterior cingulate cortex. Higher AD values were observed in the cerebellar vermis lobules in the ASD group. Groen and colleagues (2011) reported on a comparison of 17 adolescents with autism (14.4 ± 1.6 years) and 25 controls (15.5 ± 1.8 years). Participants with autism had lower FA in the left and right superior and inferior longitudinal fasciculi which lost significance after controlling for age and IQ. MD levels were markedly increased in the autism group throughout the brain.

In the two remaining voxel-wise studies, one examined adults only, and the other included subjects from the entire age range from children to adults. Bloemen and colleagues (2010) reported on a comparison of 13 adults with Asperger syndrome (39.0 ± 9.8 years) and 13 controls (37.0 ± 9.6 years). Adults with Asperger syndrome had lower FA than controls in 13 clusters which were largely bilateral and included white matter in the internal capsule; frontal, temporal, parietal, and occipital lobes; cingulum; and corpus callosum. Keller and colleagues (2007) reported on a comparison of 34 children, adolescents, and adults with ASD (18.9 ± 7.3 years) and 31 controls (18.9 ± 6.2 years). Participants with ASD had lower FA in areas within and near the corpus callosum and in the right retrolenticular portion of the internal capsule.

Region of Interest (ROI)

In using the ROI method, anatomical area(s) which are to be studied are traced for each individual participant, usually by hand and without knowledge of group membership, in order to

obtain averaged measures (e.g., FA, RD) within the ROI that characterize the selected region for a particular participant. Comparisons can then be made testing for significant group differences. ROI studies are particularly useful when particular brain structures, which can be readily defined, are suspected to be abnormal. By focusing on hypothesized regions, the problem of multiple comparisons is greatly reduced. At the time of this writing, there are seven DTI studies which use an ROI approach in the study of ASD. Overall, these studies demonstrate various diffusion abnormalities in most areas studied with the most common abnormality being a reduction in FA.

There are four studies which implement an ROI approach studying children with ASD. Ben Bashat and colleagues (2007) reported on a comparison of seven toddlers with autism with ages ranging from 1.8 to 3.3 years. ROI measurements in different anatomical regions revealed an increase in FA with dominance in the left hemisphere and frontal lobe. Sivaswamy and colleagues (2010) reported on a comparison of 27 children with ASD (mean age 5.0 years) and 16 controls (mean age 5.9 years) where ROIs were placed in the cerebellar peduncles. In the ASD group, there was an increase in the MD of bilateral superior cerebellar peduncles and reversal of asymmetry in FA of the middle cerebellar peduncle and inferior cerebellar peduncle. Brito and colleagues (2009) compared eight children with ASD (9.53 ± 1.83 years) and eight controls (9.57 ± 1.36 years). In the ASD group, they reported reduced FA in ROIs corresponding to the anterior corpus callosum, right corticospinal tract, posterior limb of right and left internal capsules, left superior cerebellar peduncle, and right and left middle cerebellar peduncles. Shukla and colleagues (2010) reported on a comparison of 26 children with ASD (12.7 ± 0.6 years) and 24 controls (13.0 ± 0.6 years). ASD children demonstrated reduced FA and increased RD for whole-brain white matter and ROIs corresponding to the corpus callosum and internal capsule. Additionally, there was increased MD for whole-brain white matter and ROIs corresponding to the anterior and posterior limbs

of the internal capsule. Finally, reduced AD was reported for the ROI of the body of the corpus callosum, and reduced FA was also found for the ROI of the middle cerebellar peduncle.

In the three remaining studies, analyses included subjects across the entire age range including children, adolescents, and adults. Lee and colleagues (2007) reported on a comparison of 43 individuals with ASD (16.2 ± 6.7 years) and 34 controls (16.4 ± 6.0 years) with ROIs capturing the superior temporal gyrus and temporal stem. In all examined regions, the ASD group demonstrated decreased FA and increased MD and RD. Lange and colleagues (2010) reported on a comparison of 30 individuals with autism (15.78 ± 5.6 years) and 30 controls (15.79 ± 5.5 years) with ROIs including superior temporal gyrus and temporal stem. Tensor skew, a measure of tensor shape, was used in addition to the more common metrics. In the superior temporal gyrus, reversed hemispheric asymmetry was reported for the autism group: tensor skew was greater on the right, and FA was decreased on the left. Moreover, there was also increased AD bilaterally. In the right temporal stem (but not the left), increases in MD, AD, and RD were exhibited in the autism group. Alexander and colleagues (2007) reported on a comparison of 43 individuals with ASD (16.23 ± 6.70 years) and 34 controls (16.44 ± 5.97 years) using a corpus callosum ROI. There were significant group differences in white matter volume, FA, MD, and RD which appeared to be driven by an autism subgroup with small corpus callosum volumes, high MD, low FA, and increased RD. Compared to other individuals with autism or the controls, this subgroup had lower performance IQ measures.

Tractography

Tractography studies have similarities to ROI studies, except the area of interest is defined using tractography. The results of tractography are very sensitive to the method and parameters used in creating these tract volumes; thus, great care must be taken to ensure reliability and blindness. In a manner analogous to ROI studies, diffusion metrics captured within the tract volume are analyzed. In addition, geometric properties of

the tracts can also be obtained (e.g., lengths, volumes). Comparisons can be made by averaging these measures and comparing means between groups. At the time of this writing, there are six DTI studies which utilize a tractography approach in the study of the neurobiology of ASD. Overall, studies using tractography demonstrate diffusion abnormalities in many fiber tracts, again with the most common abnormality being a reduction in FA.

There are two studies which implement the tractography approach studying children and adolescents with ASD. Sundaram and colleagues (2008) reported on a comparison of 50 children with ASD (4.79 ± 2.43 years) and 16 controls (6.84 ± 3.45 years). Tractography was performed on frontal lobe long- and short-range pathways. The ADC was significantly higher for whole frontal lobe, long- and short-range association fibers in the ASD group. FA was significantly lower in the ASD group for short-range fibers but not for long-range fibers. There was no between-group difference in the number of frontal lobe fibers (short and long); however, the long-range association fibers of frontal lobe were significantly longer in ASD group. Fletcher and colleagues (2010) reported on a comparison of 10 adolescents with autism (14.25 ± 1.92 years) and 10 controls (13.36 ± 1.34 years), performing tractography of the arcuate fasciculus (superior longitudinal fasciculus). The results showed an increase in MD in the autism group, due mostly to an increase in the RD. Both MD and FA were less lateralized in the autism group.

The remaining four tractography studies include adults with one study including participants across the entire age range. Catani and colleagues (2008) reported on a comparison of 15 adults with Asperger syndrome (31 ± 9 years) and 16 controls (35 ± 11 years). Tractography was performed on short intracerebellar connections, long-range afferent (i.e., corticopontocerebellar and spinocerebellar tracts) and efferent (i.e., superior cerebellar tracts) connections. The Asperger group had significantly lower FA in the short intracerebellar fibers and right superior cerebellar peduncles, but no difference in the afferent tracts. Conturo and

colleagues (2008) reported on a comparison of 17 adults with autism (26.46 ± 2.73 years) and 17 controls (26.08 ± 2.69 years), performing tractography of hippocampo-fusiform and amygdalo-fusiform pathways. While these pathways had normal size and shape, the right hippocampo-fusiform had reduced RD compared with controls, opposite to the whole-brain effect of increased RD. In contrast, left hippocampo-fusiform, right arcuate fasciculus, and left arcuate fasciculus had increased RD and increased AD in autism. There was a general loss of lateralization compared with controls. Thomas and colleagues (2011) reported on a comparison of 12 adults with autism (28.5 ± 9.7 years) and 18 controls (22.4 ± 4.1 years), performing tractography on callosal and visual-association pathways. Compared with the control group, the autism group demonstrated an increase in the volume of the intra-hemispheric fibers, particularly in the left hemisphere, and a reduction in the volume of the forceps minor and the body of the corpus callosum. Finally, Pugliese and colleagues (2009) compared 24 children, adolescents, and adults with Asperger syndrome (23.3 ± 12.4 years) and 42 controls (25.3 ± 10.3 years), performing tractography on the following limbic pathways: inferior longitudinal fasciculus, inferior frontal occipital fasciculus, uncinate, cingulum, and fornix. There were no significant between-group differences in FA and MD. However, the Asperger group had a significantly higher number of streamlines in the right and left cingulum and in the right and left inferior longitudinal fasciculus. In contrast, the group with Asperger syndrome had a significantly lower number of streamlines in the right uncinate.

Combination DTI

While each of the DTI methods described above has limitations when used alone, these can be overcome by using the methods in combination with one another, ideally in a synergistic manner. Kumar and colleagues (2010) reported on a comparison of 32 children with ASD (mean age 5.0 years), 12 developmentally impaired children without ASD (mean age 4.6 years), and 16 controls (mean age 5.5 years). They essentially

performed two separate analyses on the same group of participants: voxel-wise and tractography study. In the voxel-wise portion of the study, when the ASD and developmentally impaired children were compared with controls, FA was lower in the right uncinate fasciculus, right cingulum, and corpus callosum in both affected groups. There was also reduced FA in right arcuate fasciculus when ASD children were compared with controls and reduced FA in the bilateral inferior fronto-occipital fasciculus when developmentally impaired children were compared with controls. ADC was increased in right arcuate fasciculus in both ASD and developmentally impaired children. In the tractography portion of the study, the ASD group showed shorter length of the left uncinate fasciculus and increased length, volume, and density of the right uncinate fasciculus; increased length and density of the corpus callosum; and higher density of the left cingulum compared with the control group. Compared with the developmentally impaired group, the ASD group had increased length, volume, and density of the right uncinate fasciculus; higher volume of the left uncinate fasciculus; and increased length of the right arcuate fasciculus and corpus callosum. Jou and colleagues (2011) reported on a comparison of 10 ASD adolescents (13.06 ± 3.85 years) and 10 controls (13.94 ± 4.23 years). DTI data was analyzed in a synergistic manner by performing a voxel-wise comparison with follow-up tractography to identify underlying affected white matter structures. The regions of lower FA, as confirmed by tractography, involved the inferior longitudinal fasciculus/inferior fronto-occipital fasciculus, superior longitudinal fasciculus, and corpus callosum/cingulum. Notably, some volumes of interest were adjacent to the fusiform face area, bilaterally, corresponding to involvement of the inferior longitudinal fasciculus. The largest effect sizes were noted for volumes of interest in the right anterior radiation of the corpus callosum/cingulum and the right fusiform face area (inferior longitudinal fasciculus). Finally, Pardini and colleagues (2009) reported on a comparison of 10 adults with autism (19.7 ± 2.83 years) and 10 controls (19.9 ± 2.64 years). They compared

FA within orbitofrontal cortex volumes defined by tractography in addition to voxel-wise comparison of FA. The low-functioning group with autism demonstrated reduced tract volume and lower mean FA values in the left orbitofrontal cortex network compared with controls.

Multimodal MRI

While an extremely powerful technology, DTI remains an indirect probe of white matter integrity based on measuring properties of restricted water diffusion. One strategy to augment this data is to use multiple modalities in search for converging evidence supporting a particular neurobiological hypothesis. At the time of this writing, there are a total of five published studies taking a multimodal MRI approach: two combining with structural MRI, two combining with functional MRI, and one combining with both structural and functional MRI.

Ke and colleagues (2009) reported on a comparison of 12 children with autism (8.75 ± 2.26 years) and 10 controls (9.40 ± 2.07 years) using voxel-wise comparison of both white matter density (structural MRI) and FA (DTI). In the autism group, there was a decrease of the white matter density in the right frontal lobe, left parietal lobe, and right anterior cingulate. Moreover, there was an increase of the white matter density in the right frontal lobe, left parietal lobe, and left cingulate gyrus. The autism group also exhibited reductions of FA in the frontal lobe and left temporal lobe. Mengotti and colleagues (2011) reported on a comparison of 20 children with autism (7.00 ± 2.75 years) and 22 controls (7.68 ± 2.03 years) using a combination of voxel-wise comparison in gray/white matter and ROIs (corpus callosum, frontal, temporal, parietal, and occipital lobes) comparing ADC. Compared to controls, the autism group exhibited increased white matter volumes in the right inferior frontal gyrus, right fusiform gyrus, left precentral and supplementary motor areas, and left hippocampus. Moreover, there were increased gray matter volumes in the inferior temporal gyri bilaterally, right inferior parietal cortex, right superior occipital lobe, and left superior parietal lobule. Additionally, there were decreased gray matter volumes in the right

inferior frontal gyrus and left supplementary motor area. Finally, the autism group exhibited abnormally increased ADC in the bilateral frontal cortex and left genu of the corpus callosum.

Using a combination of DTI and functional MRI, Sahyoun and colleagues (2010b) reported on a comparison of 12 adolescents with autism (13.3 ± 2.1 years) and 12 controls (13.3 ± 2.5 years). DTI analysis included a tractography approach in which fiber tracking was aided by functional MRI. FA was captured within these tracts, and mean FA was compared between groups. The functional MRI included response time on pictorial problem-solving task. Autism and control groups showed similar networks: linguistic processing activated inferior frontal, superior and middle temporal, ventral visual, and temporoparietal areas, whereas visuospatial processing activated occipital and inferior parietal areas. However, the autism group activated occipitoparietal and ventral temporal areas, whereas controls activated frontal and temporal language regions. The autism group relied more heavily on visuospatial abilities as evidenced by intact connections between the inferior parietal and ventral temporal ROIs. There was impaired activation of frontal language areas in the autism group as evidenced by reduced connectivity of the inferior frontal region to the ventral temporal/middle temporal regions.

In another combination DTI and functional MRI study, Thakkar and colleagues (2008) reported on a comparison of 12 ASD adults (30 ± 11 years) and 14 controls (27 ± 8 years). DTI analysis included a comparison of FA performed 2 mm below the white/gray matter boundary. Functional MRI included a saccadic paradigm where activation was compared in error versus correct antisaccades, and in both correct and error antisaccades versus fixation, both within and between groups using a random effects model. Relative to controls, the ASD group made more antisaccade errors and responded more quickly on correct trials. The ASD group also showed reduced discrimination between error and correct responses in rostral anterior cingulate cortex and reduced FA in white matter underlying anterior cingulate cortex. Finally, in the ASD

group, there was increased activation on correct trials and reduced FA in rostral anterior cingulate, both of which were related to repetitive behavior.

Using a combination of DTI and structural and functional MRI, Knaus and colleagues (2010) reported on a comparison of 14 ASD adolescents (age range 11–19 years) and 20 controls (age range 11–19 years). Structural MRI analysis included volumetric measurements of language areas. DTI analysis included tractography to delineate a pathway between temporal and frontal language areas to compare mean FA. Functional MRI was used to divide participants into typical (leftward) and atypical (rightward) language laterality groups. Participants with typical left-lateralized language activation had smaller frontal language region volume and higher FA of the arcuate fasciculus compared to the group with atypical language laterality, across both ASD and controls. The group with typical language asymmetry included the most right-handed controls and fewest left-handers with ASD. Atypical language laterality was more prevalent in the ASD than in controls.

Future Directions

Future directions include further refinement of DTI techniques, sophistication in the integration of multiple imaging modalities, and multi-dimensional longitudinal designs. Improvements in technology include higher scan resolution, improving signal-to-noise ratio while maintaining tolerability, and developing novel metrics with higher pathological specificity. Other improvements go beyond the tensor model to examine the directional variation of diffusion in more detail (Lo et al. 2011). Tractography faces challenges in its ability to resolve multiple fiber populations in a single voxel (e.g., crossing and kissing fibers), growing usage as a more quantitative measure, and lack of standardized technique supported by gold-standard postmortem studies. While several multimodal studies have been published, there could be tighter integration of more modalities (MRI and beyond) to create novel study designs with higher synergy. The studies reviewed in this chapter are all cross-sectional; thus, longitudinal

studies would be optimal to fill in the gaps in current knowledge. In addition to longitudinal imaging across the life span, there should be longitudinal clinical assessments designed to give further meaning to imaging data.

Digital, Block-Based Coding of Robots for Students with Autism Spectrum Disorder

Victoria Knight¹ and John Wright²

¹Faculty of Education, University of British Columbia, Vancouver, BC, Canada

²School of Social and Behavioral Sciences, Marist College, Poughkeepsie, NY, USA

Definition

Background. Robotics and computer programming (i.e., coding) are becoming universal in K-12 STEM classrooms. Some educators and experts are calling coding the “new literacy” because every child will need to be literate in coding in order to excel in the twenty-first century (Burke et al. 2016). Participation in robotics and computer coding/programming have shown a wide range of benefits for typically developing children, including increasing student knowledge and participation in the practices of science, engineering, and in problem-solving and team building skills (e.g., Karp and Maloney 2013).

Coding (i.e., programming or developing) is the process of instructing a computer, app, phone, or website. **Robotics** is the field of computer science dedicated to engineering robots. Students

might be especially engaged when **coding robots** because they can use computer programming to interact with physical robots. To code a robot, students must determine the task they want the robot to complete, design the code to complete the task, and then ensure the robot receives the message in code and completes the desired task.

Block-based coding is a type of coding used primarily to teach introductory coding skills to children and includes predesigned sets of codes the child “drags and drops” from a computer program in order to create a set of instructions. These instructions can be used to run a computer program, control a robot, or manipulate a variety of technologies. One type of block-based coding editor is Ozo-blocky, which allows for students to increase the complexity of their coding skills over time, leading to learning of functions and even text-based coding. Learning these block-based coding skills could be a precursor to understanding more advanced skills, such as learning a computer programming language in which text-based coding is used (e.g., JAVA).

Research. Preliminary evidence suggests youth with autism spectrum disorder (ASD) and challenging behavior can learn how to manipulate a robot’s actions after being explicitly taught how to drag and drop code using block-based code (Knight et al. 2019a, b). High school students in the Knight et al. (2019a, b) study also created novel codes and generalized the skills in a self-directed manner by determining the steps they wanted the robot to follow, programming for those steps, and then assessing whether the robots followed the desired sequence (problem-solving if the robots did not). In a similar study, an elementary-aged student with ASD and challenging behavior was explicitly taught how to program robots by creating color sequences of code using paper and markers for the robots to follow (Knight et al. 2019a, b). In this study, the student learned how to calibrate, draw various tracks for the robot to follow, and draw a three-color code which programmed the robot to move at nitro speed. This student also generalized the coding skill to novel codes and without prompting, created his own three-dimensional paper robot, complete with numerical formulas the robot used to follow directions. None of the children in either study exhibited

challenging behavior at any time throughout the study, even when asked questions for which they did not know the answers (e.g., “Code the robot to go fast” during baseline sessions).

Why teach coding of robotics to children with ASD? Including students with ASD in coding and robotics opportunities throughout their K-12 education could lead to future hobbies, career goals, or an interest in pursuing science, technology, engineering, and math (STEM) college courses or majors. Wei et al. (2013) found individuals with ASD less likely than their typically developing peers and peers with other disabilities to enter college; however, individuals with ASD were enrolled in STEM majors at a disproportionately *higher rate* than their peers. Increasingly, the tech sector (e.g., Microsoft) is examining ways to hire the untapped talent pool of employees with ASD, including allowing performance-based interviews rather than traditional face to face ones. Many of these companies report “finding a return on their investment” in terms of hiring employees with ASD (Eng 2018). Longitudinal studies should examine whether students with ASD who are exposed to STEM skills in a similar way to the students in the current study are more likely to be successful in STEM courses, fields, and careers in their futures.

Dimensional Versus Categorical Classification

Andrew Pickles
School of Epidemiology and Health Science,
University of Manchester, Manchester, UK

Synonyms

Class versus variable; Discrete versus continuous

Definition

Is autism a distinct and discrete abnormality or is it simply the upper end of some dimension of normal human variability? Such a contrast of categorical and dimensional conceptualizations of mental health has a long history, especially relevant to the discussion about an autism spectrum and “the autisms.” It should be noted that the question conflates at least two issues: one is the contrast between discrete and continuous but the other is the implicit value judgment that is associated with abnormal and normal. The choice has broad consequences for almost all aspects of measurement, explanation, and much of treatment and policy formulation. It is also the basis of much unproductive and confused debate.

Essentially, all our clinical measurement of autism starts with sets of categorical symptoms or items, though implicit judgments about dimensional severity may be implicit in the scoring of each item. From these, the international diagnostic systems such as DSM (American Psychiatric Association [APA] 1994) spent decades refining rules for combining these items into categorical diagnostic categories. Screening questionnaires (e.g., Charman et al. 2007) commonly start with a similar item set and form total scores that might be considered a dimension. However, the items chosen commonly identify clear abnormality (high threshold or difficult items in the terminology of psychometrics), generate strongly non-normal item-total distributions when applied to a general population, and, through use of cut points, are intended to increase the proportion or probability of caseness rather than to provide a metric. They are not intended to differentiate among the majority who fall within the normal range. By contrast, questionnaires such as the Autism Quotient (e.g., Wheelwright et al. 2010) have items with a range of difficulties and are quite explicitly orientated toward measurement of an autism-related dimension. Questions then arise as to whether the variation that is being differentiated among the normal and supernormal is the same dimension as the variation being

differentiated among the abnormal or whether instead we have a mixture of normal and abnormal populations. Some formal tests have been proposed (e.g., Meehl 1995).

The use of a categorical diagnostic tool and a separate dimensional severity has the potential to lead to inconsistencies, a problem that can be resolved if both are derived from the same instrument, for example, the Autism Diagnostic Observation Schedule (Gotham et al. 2009). It is however crucial to distinguish a dimensional severity measure that relates to symptom abnormality from one that relates to level of impairment. While these are correlated, they are not the same.

So should autism be treated as a category or as a high score on a dimension? The arguments of Pickles and Angold (2003) imply that while a dimensional perspective may be more appropriate when considering some aspects of autism, such as when assessing treatment outcome effects, a categorical perspective may be better, even necessary, when considering another, notably treatment eligibility. Whether that dimension should be severity or impairment will depend on the circumstance.

DMG

Definition

Dimethylglycine (DMG) is a natural substance thought to inhibit the buildup of certain amino acids in the body and enhance the immune response in children with ASD. It is a derivative of the amino acid, glycine. It is found in foods, such as beans, grains, and liver.

DMG supplementation has been proposed as a treatment for autism. Anecdotal reports have suggested that use of DMG improved social behavior, frustration tolerance, speech, and reduced aggressive behavior in individuals with autism. However, two randomized clinical

Definition

In criminal law, the defense of diminished responsibility reduces a person's liability in connection with the killing of another if it can be argued that they were suffering from an "abnormality of mind (whether arising from a condition of arrested or

retarded development of mind or any inherent causes or induced by disease or injury) as substantially impaired his mental responsibility for his acts and omissions in doing or being a party to the killing” (Homicide Act (England & Wales) 1957). As this definition from English law indicates, this defense can only be used in connection with charges of murder and, if successful, reduces a person’s culpability such that they are found guilty of the lesser charge of manslaughter rather than murder. It is particularly useful in this context as there are many “disposal” options available to the court for a charge of manslaughter, whereas murder carries the mandatory life sentence.

The defense itself was first recognized under the common law in Scotland and is recognized in several jurisdictions across the globe, including several states in the USA; certain territories in Australia, Hong Kong, and Singapore; and several Caribbean countries. Moreover, in certain jurisdictions without this defense, there have been a number of cases described where a defense of “lack of intent” has been advanced on the grounds of a mental disorder not amounting to insanity, essentially amounting to the same thing as a diminished defense.

It is important to contrast diminished responsibility with defense of insanity, which states that if a person, at the time of the act or omission, was, due to a severe mental disease or defect, unable to appreciate the nature or quality of their act, then they cannot be held criminally responsible for their behavior. As a result, and in contrast to the defense of criminal responsibility, they are deemed to be “not guilty.” Both diminished responsibility and insanity are therefore interpreted at the level of a person’s mens rea (i.e., their ability to form a “guilty mind”).

The relevance of this defense to individuals with ASDs will therefore only really arise in connection with allegations of murder. Such an occurrence will be extremely uncommon, and at the time of writing, no case law on the use of this defense for an individual with ASDs is available.

Definition

Diphenhydramine (generic name) is also known as Benadryl[®]. Diphenhydramine acts by blocking the effect of histamine on the H1 receptor site. Diphenhydramine inhibits most responses of smooth muscle to histamine. It acts as a vasoconstrictor by inhibiting the vasodilator effects of histamine.

Diphenhydramine is used to provide relief to allergic symptoms caused by histamine release, for sedation, as prevention of motion sickness, as an antitussive, as treatment of phenothiazine-induced dystonic reactions, as adjunct to epinephrine in the treatment of anaphylaxis, and topically for relief of pain and itching.

Diphenhydramine is often used to control agitation or aggression in children; however, it does not have an FDA indication for this use.

Pharmacodynamics/Kinetics:

- Onset of action: Maximum sedative effect: 1–3 h
- Duration: 4–7 h
- Distribution: V_d : 3–22 L/kg
- Protein binding: 78%
- Metabolism: Extensively hepatic n-demethylation via CYP2D6; minor demethylation via CYP1A2, 2C9, and 2C19; smaller degrees in pulmonary and renal systems; significant first-pass effect

- Bioavailability: Oral: ~40–70%
- Half-life elimination: 2–10 h; elderly: 13.5 h
- Time to peak, serum: 2–4 h
- Excretion: Urine (as unchanged drug)

Side Effects

Since diphenhydramine acts by blocking the effect of histamine on the H1 receptor site, it can cause significant anticholinergic side effects such as ataxia; loss of coordination; decreased mucus production; consequent dry, sore throat; xerostomia or dry mouth with possible acceleration of dental caries; cessation of perspiration; consequent decreased epidermal thermal dissipation leading to warm, blotchy, or red skin; increased body temperature; pupil dilation (mydriasis); consequent sensitivity to bright light (photophobia); loss of accommodation (loss of focusing ability, blurred vision (cycloplegia)); double vision (diplopia); increased heart rate (tachycardia); tendency to be easily startled; urinary retention; diminished bowel movement, sometimes ileus; increased intraocular pressure; and shaking.

In high enough doses, diphenhydramine can cause a cholinergic delirium (children and elderly are more prone), and may include confusion, disorientation, agitation, euphoria, or dysphoria; respiratory depression; memory problems; inability to concentrate; wandering thoughts; inability to sustain a train of thought; incoherent speech; wakeful myoclonic jerking; unusual sensitivity to sudden sounds; illogical thinking; visual disturbances (periodic flashes of light, periodic changes in visual field, restricted vision); visual, auditory, or other sensory hallucinations (warping or waving of surfaces and edges, textured surfaces, “dancing” lines, “spiders,” insects); and, rarely, seizures, coma, and death.

Diphenhydramine may cause paradoxical excitation in young children.

Its chemical name is 2-(Diphenylmethoxy)-N, N-dimethylethylamine hydrochloride, and it has a molecular weight of 291.82. The molecular formula is $C_{17}H_{21}NO \cdot HCl$.

Definition

Diphenhydramine is a histamine H₁ receptor inverse agonist/antagonist as well as a potent

muscarinic acetylcholine receptor antagonist. Being blood–brain barrier permeable, diphenhydramine’s action on CNS H₁ receptors results in a drowsy state. While this drowsy state may be beneficial to ASD patients with sleep problems, there is no evidence indicating diphenhydramine effectiveness in treating ASD’s core symptoms. The drug is most commonly used for allergies and common cold. Side effects may include nausea, vomiting, drowsiness, dizziness, loss of appetite, headache, muscle weakness, and excitement.

DIR Model (Developmental, Individual Difference, Relationship Based): A Parent-Mediated Mental Health Approach to Autism Spectrum Disorders, The

Serena Wieder
Profectum Foundation, Mendham, NJ, USA

Definition

The *Developmental, Individual Difference, Relationship-Based* model of intervention (DIR)

provides a developmental framework for interdisciplinary assessment and parent-mediated intervention for autism spectrum and related disorders. This comprehensive model utilizes affect-based interactions and experiences tailored to individual differences to promote development. “D” refers to developmental capacities for shared attention and regulation, engagement across a wide range of emotions, two-way communication, and complex social problem solving which underlie the development of symbol formation, language, and intelligence. Intervention starts with pleasurable synchronous interactions between children and parents, the heart of relationships, which support progress. “I” refers to individual differences related to sensory reactivity and regulation, visual-spatial and auditory/language processing, and purposeful movement. Challenges in these neurobiological factors can make it difficult to participate in the emotional interactions that enable mastery of the developmental capacities (“D”). “R” refers to relationships with caregivers that are the vehicle for affect-based developmentally appropriate interactions. DIR pioneered parent-mediated intervention because of *parents’ ongoing opportunities to support their child’s* everyday functioning to carry out emotionally meaningful goals and provides the essential relationship every child needs. Cultural and environmental influences are also considered. By taking all three dimensions of DIR into account, the foundation for functioning, learning, and relating to others in meaningful ways is established. Current developmental science’s shift away from behavioral reductionism to a relational developmental perspective highlights DIR’s original dynamic and systems model where its three dimensions mutually influence each other throughout the life span.

DIR is commonly known as *Floortime*, the heart of DIR’s intervention. Floortime is both a philosophy and specific technique where caregivers follow the child’s natural emotional interests and create states of heightened pleasure in playful interactions tailored to the child’s unique motor and sensory-processing profile to strengthen the connection between sensation, affect, and motor action. Connecting words to underlying affects that give them purpose and

meaning leads to the formation of symbols, imaginative play, and reflective conversations. Additionally, semi-structured problem solving and social activities; play dates, language, sensory-motor, and visual-spatial therapies; educational programs; family support; and augmentative and biomedical interventions make DIR a comprehensive model. The child’s evolving DIR profile determines the individualized intervention as he progresses. While DIR emphasizes early identification and early intervention, it guides developmental intervention at all ages (Greenspan and Wieder 1998, 2006, 2011; Wieder 2011; Wieder and Greenspan 2001). As an infant mental health model, DIR is strength based; focuses on the child’s emotional life and challenges; addresses anxiety, emotional and behavioral regulation, parent stress, and depression; and engages in reflective practice.

Historical Background

The components of the DIR Model have long theoretical, clinical, and research traditions. Developmental frameworks go as far back as Freud, Erikson, Piaget, Anna Freud, and Mahler and were enhanced by the clinical reports of Spitz, Bowlby, Winnicott, Fraiberg, Lourie, Provence, and others who described the critical impact disrupted and impoverished environments had on early relationships and development. Soon the nuances and bidirectionality of parent infant interaction came under scrutiny as Tronick, Feldman, Fonagy, and others studied synchrony, contingency, affect attunement, match-mismatch, and repair. The importance of nurturing responsive parents and strong parent-child relationships that could protect the family from the disruptions of stress and harmful life events, as well as social emotional development, shaped the new field of infant mental health. Meanwhile, Escalona, Ayres, Brazelton, and others were identifying biological influences in development. This coincided with rejection of psychogenic theory blaming parents for their children’s autism implied by Kanner, Asperger, and Bettelheim in prior decades and opened the door to understanding individual differences (Greenspan et al. 2001; Wieder 2011).

Developmental processes underlie every aspect of experience. Far from automatic, far from milestones, development is a process that captures the essential pathways to functional emotional capacities, which, in turn, contribute to mental health and resilience. This chapter will describe how the DIR Model by Greenspan and Wieder integrated IMH into development in a relationship-based intervention model emphasizing therapeutic pathways that facilitate affect signaling, shared and joint attention, reciprocal communication, problem solving, and symbolic process. It will illustrate how symbolic expression reflects capacities for the full range of emotions within the reciprocal relationship between the child's developmental capacities and the caregiving environment.

The initial formulation, the developmental structuralist theory, developed during an NIMH preventive intervention research study of multi-risk families, described the processes that organize experience at successively higher levels and provide the structure for development (Greenspan et al. 1987; Greenspan and Lourie 1981). As more children at risk for disorders in relating and communicating were identified, this model began to serve children with autism and other special needs providing the first relationship-based developmental approach recognizing individual differences and how emotions impact cognitive and language abilities, as well as social and self-regulation skills, and became known as DIR (Greenspan and Wieder 1998, 2006, 2011).

Rationale or Underlying Theory

Autism's deficits relate to the inability to interact with emotional signals, gestures, and vocalizations, and maintain these interactions with others. DIR hypothesizes these deficits stem from a compromised capacity to connect emotions or intent to motor planning/sequencing, sensations, and later to early forms of symbolic expression of intent or emotions (Greenspan and Shanker 2004; Greenspan and Wieder 1998, 2006). Usually, an

infant connects the sensory system to the motor system through affect, e.g., seeing the caregiver's smiling face or hearing her wooing voice entices the infant to turn and look and listen and smile back. Through many of these interactions, the infant begins to recognize patterns as they share attention, take pleasure in interactions, read each other's cues, and respond to each other over and over again through gaze, vocalizations, and gestures. By the end of the first year, the infant recognizes variations in his caregiver's affect as well as his own feelings related to love, anger, feeling proud, disapproved of, etc. By the second year, these patterns lead to sense of self as purposeful and differentiated sense of others. By the third year, these interactions enable a child to form and give meaning to symbols leading to higher levels of thinking. When challenges with sensory-motor, language comprehension, and visual-spatial knowledge derail this process, affect must be brought in to strengthen connections and enable simultaneous looking, listening, and moving while engaging in meaningful problem-solving interactions, through heightened states of pleasure and other affects. Longer chains of co-regulated affective gesturing will enable the child to recognize variations in the caregiver's gestures, facial expressions, and tone of voice and become aware of his anxiety and repetitive behavior. The relationship becomes the vehicle for affect that transforms labels into meanings leading to symbolic thinking and more complex and abstract reasoning (Greenspan and Shanker 2004; Greenspan and Wieder 1998; Wieder and Greenspan 2003).

DIR theory identifies six fundamental capacities that *emerge* in infancy and *expand* in duration, range, and stability as the child develops. These capacities are necessary for functioning across the life span and can be observed at any point in time.

1. *Regulation and Shared Attention (Between Infant and Caregiver)*. From birth to 3 months, an infant's capacity grows for calm, focused interest in the sights and sounds of the outer

world while she begins to share her interests with the caregiver.

2. *Forming Attachments and Engaging in Relationships.* During the next first 4 months, infants and parents become more intimate as they interact with warmth, trust, and intimacy. They each use their senses to enjoy each other through looks, hugs, songs, and dancing together. Over time, the infant will need to remain related and engaged across the full range of emotions, even when disappointed, scared, angry, or stressed.
3. *Intentional Two-Way Affective Communication.* Between 4 and 10 months, purposeful, continuous flow of interactions with gestures and reciprocating emotions gets underway. The infant begins to act purposefully, more aware of her body and the functions it can perform. As the infant gains motor control over her body and intent, she is better able to communicate her desires. With emerging abilities to reach, sit and turn, crawl and creep, and give, take or drop objects, the infant's awareness of the interpersonal world develops, as does awareness of her body in space and in relation to others who may be moving.
4. *Complex Social Problem Solving.* Between 9 and 18 months, an infant has learned the back and forth rhythm of interactive emotional signaling and begins to use this ability to think about and solve problems that are emotionally meaningful to get what he wants, such as pulling mommy to the door to go outside and play. All of the child's senses work with his motor system as he interacts with others to solve problems. Difficulties arise when he encounters new difficulties to solve as experience expands.
5. *Emotional Ideas.* Between 18 and 36 months, the toddler begins to represent or symbolize intentions, feelings, and ideas in imaginative play and/or language, using gestures, words, and symbols. The toddler now calls on a toy phone, sets up a picnic or tea party, takes the sick baby to the doctor, or repairs his car before driving. These first ideas come from

experiences in real life that are enacted in pretend dramas as the child experiments with different roles and feelings.

6. *Emotional Thinking, Logic, and Sense of Reality.* At about three, the child begins to combine ideas to tell a story as he develops more logic and understanding of himself and others. His stories use imaginative characters and animal figures that talk and may have magic as he discovers he needs more power to encounter the fears and conflicts in life, but reasoning skills click in to elaborate sequences, and stories become increasingly logical and realistic. Over the next few years, the child's emotional and mental abilities move toward abstract thinking, and he develops the ability to distinguish reality from fantasy, self from nonself, and one feeling from another and makes distinctions concerning time and space.

Level six later expands to:

7. *Multicausal and Comparative Thinking.* The child "deepens the plot," explores multiple motives, gets opinions, and compares and contrasts ideas. The child can step into "your shoes" and predicts what you will do based on "affect cues" related to deception, fairness, and justice.
8. *Relativistic or Gray-Area Thinking.* Here, the child differentiates more of his thoughts, rather than thinking only in "black and white" terms. For example, the lion may pay a price for killing the zebra who breaks his leg before being devoured. The child now considers different possibilities and contingencies and is aware of different outcomes and of how he would feel under different circumstances.
9. *Self-Reflection or Thinking Using an Internal Standard.* Now the child has a sense of herself; she can look at and reflect on her performance and feelings. She can question why she is feeling a certain way and contrast this with how she usually feels, or she can compare her current efforts with earlier ones. This kind of thinking

allows her to make inferences about herself and others and create new choices and ideas.

Each of these capacities can be framed as indicators of emotional development throughout life. For example, engagement builds on shared attention with another and must withstand negative feelings, as well as love, trust, and security. Gestures, expressed through tone of voice, movement, facial expressions, and body language continue to be the fundamentals of communication giving meaning to words and negotiate acceptance, approval, ambivalence, and rejection. Complex social problem solving relates to perspective taking and reciprocity that underlie cooperation and collaboration. As language and symbolic development emerge, it is possible to pursue the inner experience of children as they use words and play to express emotions, develop and bridge ideas in logical sequences, and develop reality testing. The progressive levels of thinking are a reflection of emotional thinking and the development of self.

Goals and Objectives

The goal of the DIR model is to enable children on the autism spectrum to form a sense of themselves as intentional, interactive individuals, who can develop cognitive, language, and social and emotional capacities. This calls for the mastery of six functional developmental levels and comprehensive interventions that treat problems related to gaps or variability in these capacities.

Specific objectives:

- To identify the degree to which each developmental level is mastered fully, partially, or unmastered and how stable or consistent. The critical principle is to engage the child at his or her level and to help the child master that level and subsequent levels. When a child has partial mastery of a higher level, e.g., using ideas, but is not fully engaged or interactive, he still needs work at the earlier levels.
- To identify and treat the bioneurological regulatory, sensory, and motor-processing challenges that effect developmental processes.
- To identify gaps in daily adaptation and expected competencies in executive functions.
- To identify family needs for counseling, functioning, and advocacy.
- To organize comprehensive individualized programs that apply principles of affect-based interactions throughout all interventions to support meanings and comprehension.
- To use developmentally appropriate practices which support child initiation, intentionality, communication, and discovery.
- To keep intervention dynamic and flexible, modifying as needed to support rate of progress.

Treatment Participants

This model provides a road map for the treatment of ASD and other developmental, learning, and emotional challenges and diagnoses across the life span. This widespread applicability is possible because it is based on a theory that focuses on capacities fundamental to the development of all individuals. It is also a comprehensive model with a range of interventions that can be tailored to specific underlying sensory processing, motor, and learning challenges, as well as family and cultural factors. Since autism is so heterogeneous, DIR can guide each family to identify the most appropriate program for the child and family based on their individual profiles and helps set priorities. This theory of development is especially useful for early identification in infancy when capacities for regulation and shared attention, engagement, and communicative intent begin and red flags become evident. The intervention begins as soon as challenges are evident or at risk. Infant siblings of children with autism should be monitored. With older ages (children, adolescents, and adults) intervention ensues when gaps in development are identified, rate of progress is less than expected, core capacities need strengthening, and anxiety, stress, and social emotional difficulties arise. DIR intervention can support

other interventions and educational challenges and especially supports families.

Treatment Procedures

Appropriate assessment of all functional areas requires multiple sessions with the child and family. A senior DIR clinician and/or multidisciplinary team determines which developmental capacities have been mastered fully, partially, or not at all and how individual differences in sensory modulation, processing, and motor planning effect each level and underlie particular symptoms, behaviors, and learning challenges. These sessions begin with parent discussions, two 45-min observations of child-caregiver and/or clinician-child interactions, developmental history and review of current functioning, family functioning, prior diagnostic and educational assessments, current programs, consultation with speech and language, occupational, physical, and arts therapists, educators, developmental-pediatricians, optometrists, and mental health colleagues when indicated. Structured tests (ADOS, neuropsychological, educational, speech and language, OT, PT, etc.) are recommended as needed, rather than routine bases, and biomedical evaluation. Intervention planning and priorities are set with the family and team.

DIR is unique in its comprehensiveness, its developmental focus, the role of the family, its emphasis on emotional and symbolic development, and its long-term developmental perspective. As a dynamic model, it is flexible and changes as the child progresses moving onto typical activities. There is no attempt to fit the child into a program, and the specific interventions and frequency depend on individual needs. While these therapies are common to other treatments, DIR provides the unifying goals and principles for an integrated approach. The sessions may be individual and/or group based, in schools or therapy offices, and parents participate (Greenspan and Wieder 2000, 1998, 2006).

DIR interventions include the following:

- Floortime starts with 4–6 daily *spontaneous unstructured “play”* sessions of 20–30 min (15 h weekly) provided by parents and caregivers that focus on obtaining a continuous flow of synchronous interactions as the child climbs the developmental ladder, e.g., 20–50 circles of communication during preschool years. Teachers, therapists, and Floortime players can provide these experiences. Key elements include observe child’s interests, wait for his initiation and response, follow his intentions, and engage in what gives him pleasure using affect cues to sustain shared and joint attention; expand back and forth interactions by helping child do what he intends, becoming playfully obstructive, and increase problem solving in gestures or words to get the child to further elaborate his intent and reciprocity. The parent does not change topics or direct but works within the child’s interests to deepen engagement and expand ideas at pre-symbolic and symbolic levels where imaginative play focuses on emotions and abstract thinking. These Floortime principles also inform all education and therapies so that children are maximally interested and engaged in learning interactions.
- Semi-structured problem-solving interventions and routines. The child with autism may not benefit just from exposure to experiences and needs mediation and systematic implementation. Natural learning from the environment gets derailed by constricted interests, repetitive behaviors, poor imitation, poor auditory and visual-spatial comprehension, and motor planning difficulties (praxis), as well as hypersensitivity and/or under-responsiveness. Opportunities are created daily to get the child to tune into his environment and think when his expectations are challenged, and changes poses a problem for him. These situations are always meaningful and relevant to his emotions such as desire for more or less of something; concern something he is missing or broken, or not finding what he wants in usual places; feeling challenged when needing better motor skills to open containers, or unwrap books or toys; and having to pack his

backpack, serve as a messenger, follow multiple directions, and get ready independently for routines, and other executive function tasks. Reasoning is inserted to comprehend the problem and helps the child feel that the new expectations are not arbitrary, with co-regulated interactions to deal with frustration or disappointment, as well as excitement and success. The challenge increases as the child progresses and involves more elaborate sequences of actions and thoughts with the larger goal of helping child develop competencies off of real-life experiences. In the DIR model, these competencies are part of the Foundational Capacities for Development (FCD) (Wieder and Wachs 2012).

- Social Games and Activities. When meaningful and fun, typical social activities can be practiced with an adult and then peers, e.g., songs and movement such as ring-around-the-rosy, red light-green light, red rover, relay races, treasure hunts, or tag. Secondary goals are to help the child learn to negotiate, make deals, learn turn taking and chance games, and resolve conflicts. At older later, social thinking and group activities and therapy may be useful.
- Play dates and social activities with peers to form friendships and spontaneous interactions, sharing ideas, and negotiations. Number per week depends on age of the child.
- Sensory Motor/Visual-Spatial Activities for several hours daily. Most children with autism have motor planning, coordination, or executive function challenges and rely on memory to stay oriented in space. Many have reduced muscle tone and movement/discriminative movement difficulties. Ocular motor and other visual-spatial processing challenges contribute to attention and learning difficulties as well as daily adaptation. Therefore, intensive daily practice to strengthen these areas is beneficial. Activities range from specific fun exercise routines, involving running, jumping, climbing, chase, and range from solo sports, gymnastic, biking, swimming, or track, to interactive ball sports. These activities support competence and fun and are opportunities for interaction and negotiation.
- Individual and group language, occupational, physical, visual-spatial, and creative art therapies are determined by individual needs of the child. DIR therapists maintain a developmental perspective, include parents in the sessions, and guide home activities between sessions.
- Educational programs range from inclusion in regular education and public and private special education with varying degrees of inclusion, hybrid programs of school- and home-based intervention, tutoring programs, etc. These programs vary in the level of structure provided and are selected on the basis of which setting will best insure comprehension, social interaction, and learning.
- Augmentative and assistive technologies as indicated.
- Family counseling to help parents implement interventions, plan transitions and prepare for adulthood, support family functioning, and provide advocacy when needed.
- Developmental psychotherapy and mental health intervention may be indicated as children and adolescents get older and are struggling with anxiety, depression, mood disorder, etc. Some may also benefit from medications.
- Consideration of stress-related interventions including nutrition and diet, sleep, biomedical interventions, and when indicated, medications addressing regulation and anxiety, possible seizures, impulsiveness, and attention disorders.

Efficacy Information

DIR and Parent Mediated Intervention (PMI) provide research evidence for autism treatment targeting core deficits by strengthening essential relationships every child needs and demonstrates long-term benefits. Research with at risk infant siblings of children with autism under 1 year of age further highlight the potential value of prodromal relationship interventions. Major studies are reviewed here.

The PLAY Project, a DIR-based intervention that found large treatment effects for parent-child interactional behaviors in 2007, was followed by a study of 128 randomized preschool aged children who received 3 h monthly meetings using coaching, modeling, and video feedback for 1 year with a home consultant. Parents also provided 15 h of Floortime weekly and all children received community services. Large treatment effects were reported for parent-child interactional behaviors, improved diagnostic categories on ADOS, and reduced autism symptomology along with reduced parent stress and depression. No differences were found on IQ or language scores (Solomon et al. 2007, 2014).

Another DIR evidence-based study at York University compared 12-month DIR/Floortime treatment for 51 children ages 30–51 months with community standard and found significant gains in initiation of joint attention, enjoyment, fewer ADOS symptoms, changes in interaction skills, and less parent stress and depression (Casenhiser et al. 2011). A subsequent analysis of communicative language acts in conversations with parents was significant, whereas language tests were not (Casenhiser et al. 2014). Parent stress has been reported by others and this study, as well as the PLAY Project, highlights the importance of relationship-based interventions in reducing stress and depression as parents are appreciated for their central to the intervention process.

The Preschool Autism Communication Trial (PACT) offered PMI 2 h, twice monthly for 6 months, and monthly for the next 6 months to randomized group of 152 children between 2 and 4–11 years. Intervention targeted social interactions and communication, was video aided, and provided plans for daily play at home after each session. Significant findings were reported for reduced severity of autism symptoms and increased parental synchronous response to child, child initiations, and shared attention. Effects on language and adaptive functioning in school were small (Green et al. 2010). Although no further intervention was offered, a rare long-

term follow-up study of 80% of the children 6 years later found the PMI group continued to show less severe symptoms, with improved social communication skills and reduced repetitive behavior, but no differences in language or anxiety (Pickles et al. 2016).

These researchers also conducted the iBasis (Intervention British Autism Study of Infant Siblings), the first pre-emptive parent-mediated intervention with 54 infants at familial risk. The 5-month home-based video-aided intervention (9–14 months) reduced the severity of subsequent prodromal autism symptoms over the period to 39-month follow-up, as well as producing positive impact on dyadic parent–infant interactions and child attention and initiation. They focused on interpreting the infant's behavior, recognizing intentions, and enhancing sensitive responding, emotional attunement, and patterns of verbal and nonverbal interaction (Green et al. 2017). Replication of these studies is underway.

Neuroscientists in the IBIS (Infant Brain Imaging Study) Network are using fMRI images from high risk siblings and low risk infants to develop early prediction models, “neural signatures,” for autism. Images found specific brain differences at 6 months that predicted autism at 24 months in group data. In a study of typical and high risk 260 babies, the high risk group showed neural inefficiencies in the right auditory cortex (processes speech sounds) and by 12 month in areas critical for language, touch, and self-awareness. Early brain and behavior changes in autism can be detected before symptoms appear and likely have downstream cascading effects, producing later manifestations and later brain changes in autism. Lewis reported, “Without processing efficiently and pruning, the brain just passes on noise.” They found 17% of high risk infants were diagnosed at 2, and 1.3% of the control group (Lewis et al. 2017). While these prediction models have potential public health implications, they need to be replicated and are not yet available for clinical application now.

Another IBIS prospective longitudinal intervention study of infant siblings used

electrophysiological (EEG) and habituation measures to target social attention. Measures of 33 high risk infants were taken at 6, 12, 18 months in a randomized control study. Between 9 and 11 months, the 19 randomized intervention group received *Promoting First Relationships*, a parent-mediated intervention of 10 weekly sessions, and showed improved social attention in reduced habituation times to face versus object stimuli and greater increase in frontal EEG theta power, closer to the normative responses of matched low risk controls. Replication is necessary, but results suggest relationship-based intervention has the potential to alter the brain systems underpinning social attention and improve outcomes (Jones et al. 2017). On another frontier, Torres et al. (2016) used new mathematical analytics to profile growth data longitudinally from 36 newborn babies with and without complications over 5 months using sensors that hinted at less overall motion in the infants at risk, and detected very early stunting in the development of voluntary neuromotor control flagging risk of neurodevelopmental derailment and potential of early motor-based intervention in high risk infants for autism. These recent findings hold promise for relationship based intervention changing trajectories when identified very early to improve outcomes for children with autism.

Other methods and research also support elements of DIR's complex model. Responsive parent-child interactions have been found to improve social engagement and communication (Gernsbacher 2006; Gutstein 2005; Mahoney and Perales 2005; Prizant et al. 2003; Schreibman and Koegel 2005; Vismara and Rogers 2009). Studies on joint attention, emotional attunement, and play reported gains in language and symbolic thought (Kasari et al. 2006; Kasari et al. 2008a; Mundy et al. 1990). Following a child's lead improved communication as well as language development over long-term periods (Schreibman and Koegel 2005; Siller and Sigman 2002). The strength of relationships and attachment is tied to parent's sensitive responsiveness just as with typical children (Capps et al. 1994; Oppenheim 2009; Rogers et al. 1993). The Early Start Denver model reported affectively engaging social interactions,

improved IQ, language, social interaction, initiative, behavior, and adaptive skills and decreased severity of ASD symptoms (Rogers and Dawson 2010). A 10- to 15-year follow-up study of a subset of 16 boys between 12 and 17, who received preschool DIR intervention, showed empathetic, creative, abstract, and reflective adolescents (Greenspan and Wieder 2005). There is still no definitive evidence on any one method being better than others, but relationships belong to everyone and should be part of all interventions.

Outcome Measurement

DIR studies utilize the standard outcome measures in autism research, including the Autism Diagnostic Observation Scale (ADOS), Achenbach Child and Adolescent Behavior Checklists, BASC (Behavior Assessment System for Children), Greenspan Social-Emotional Growth Chart, Mahoney Maternal and Child Behavior Rating Scales, Mullen Scales of Early Learning, MacArthur CDI, Reynell Developmental Language Scales, Vineland-II, Parenting Stress Index, CES-D Depression Scale, Functional Emotional Assessment Scale, Functional Emotional Developmental Level rating scales, sensory motor profiles related to individual differences, symbolic play scales, and clinical reports.

Qualifications of Treatment Providers

Treatment is provided by multidisciplinary licensed/credentialed professionals who complete a multiyear certificate process to develop competencies within their discipline. They coordinate, consult, and/or oversee intervention teams and supervise paraprofessional Floortime players and assistants who implement specified activities in schools, social activities, and homes. Professionals include clinical and developmental psychologists, regular and special educators, and speech and language, occupational, physical, movement, and creative arts therapists. Senior professionals coordinate teams. Parents work

side by side with the therapists, are coached to provide Floortime, implement the home programs, and have free access to the Profectum Parent Toolbox series of training webcasts (PPT 2017). Developmental pediatricians, pediatricians, child psychiatrists, neurologists, nutritionists, and other specialists are consulted as needed.

Direct Instruction

Rebecca DeAquir
The Center for Children with Special Needs,
Glastonbury, CT, USA

Definition

Direct instruction is a general term used to describe the explicit teaching of a skill set and was developed by Siegfried Engelmann, Wesley Becker, and colleagues. It is a teaching model that focuses on systematically planned lessons and

clearly defined teaching procedures. It often involves breaking down instructional targets into smaller components and using a scaffolding approach to teach material. Direct instruction emphasizes the explicit teaching of skills and requires that students consistently demonstrate mastery before moving on to new material. Direct instruction requires that students actively participate in learning and necessarily involves meaningful teacher-student interaction.

Direct Observation

Anne Holmes

Eden Autism Services, Princeton, NJ, USA

Definition

Direct observation, also known as observational study, is a method of collecting evaluative information in which the evaluator watches the subject in his or her usual environment without altering that environment. Direct observation is used when other data collection procedures, such as surveys, questionnaires, etc., are not effective; when the goal is to evaluate an ongoing behavior process,

event, or situation; or when there are physical outcomes that can be readily seen.

Direct observation can be overt, when the subject and individuals in the environment know the purpose of the observation, or covert, when the subject and individuals in the environment are unaware of the purpose of the observation.

Structured direct observations are most appropriate when standardized information needs to be gathered, and result in quantitative data. Unstructured direct observation looks at natural occurrence and provides qualitative data, such as that used when administering the Childhood Autism Rating Scale (CARS), the Checklist for Autism in Toddlers (CHAT), and the American Psychiatric Association's Diagnostic and Statistical Manual, 4th Edition (DSM-IV).

Data recording for direct observation includes narrative notes, video or photographs, recording checklist (yes/no), observation guidelines (printed forms with space to write notes), and combinations of the above. Direct observation provides the highest degree of ecological validity but lowest degree of experimental control. The value of direct observation is directly related to the evaluator's ability to capture detail, determine what is important, and interpret what has been observed. Because autism is a disorder that is diagnosed and individuals are evaluated through behavioral observation, direct observation is a critical evaluative tool that affords an objective perspective of the individual's profile.

Direct Observation Scales

Tina Newman
The Center for Children with Special Needs,
Glastonbury, CT, USA

Definition

Direct observation scales are structured instruments used to collect first-hand information regarding observable behaviors. They contrast to scales that provide indirect accounts, such as rating scales, report forms, or interviews with parents, caregivers, or teachers regarding behaviors of an individual, although both provide important information. Direct observation scales are critical in both diagnosis and intervention with children with autism spectrum disorders. While these scales can vary in format, they share common characteristics, including having a structure as to what is attended to in the observation and what is coded. Thus, they are not simply a description of what an individual is doing. For autism spectrum disorders, the behaviors central to the diagnosis are most often the target of direct observation scales (e.g., eye contact, social initiations, conversational turn-taking) and behaviors that interfere with functioning and are the targets of intervention (e.g., aggression or bolting). Direct observation scales can be more or less structured in how the observation situation is set up and how the data is collected. Some direct observation scales

provide a set of semi-structured activities and record and code observed target behavior within those activities, while others provide a structured means to record and code direct observations in the natural environment. A number of direct observation scales have been developed for diagnostic purposes including those that provide semi-structured activities in which to record and code observations, such as the widely used Autism Diagnostic Observational Schedule (ADOS; Lord et al. 2001) and the Autism Observation Scale for Infants (AOSI; Bryson et al. 2000). For assessment of interfering behaviors for the purpose of treatment planning, direct observation scales are often used during a functional behavioral assessment (FBA). These direct observations are most often conducted in the natural environment and data is collected with a very systematic methodology. Different types of data can be collected during an FBA including interval, frequency, duration, latency, and antecedent-behavior-consequence (ABC) data.

Disability

Michael Miklos
 Pennsylvania Training and Technical Assistance
 Network, Harrisburg, PA, USA

Synonyms

[Affliction](#); [Detriment in skill](#); [Exceptionality](#); [Incapacity](#); [Relative weakness in an area of functioning](#)

Definition

In common terms, it is the condition of being unable to perform a skill as a consequence of physical or mental incapacity. It may suggest impairments, limitations, or restrictions on performing certain activities. Autism is one category of disability under special education regulations (IDEA 2004). Other categories of disability include intellectual disability, a hearing impairment (including deafness), a speech or language impairment, a visual impairment (including blindness), a serious emotional disturbance (referred to in this part as emotional disturbance), an orthopedic impairment, traumatic brain injury, other health impairments, a specific learning disability, deaf-blindness, or multiple disabilities. A child with a disability under IDEA (2004) needs special education and related services. Additionally, the law provides for services for children with a disability aged 3–9, to include a child experiencing developmental delays as measured by appropriate diagnostic instruments and procedures, in one or more of the following areas: physical development; cognitive development; communication development; social or emotional development; or adaptive development; and by reason thereof, needs special education and related services. In some situations, children with a disability may be said to present a developmental delay if members

of the IEP team are not certain that the individual meets the criteria for autism.

Discontinuous Data Collection

Shaunessy Egan and Kerri Booth
 Center for Children with Special Needs,
 Glastonbury, CT, USA

Synonyms

[Discontinuous measurement](#); [Time sampling procedures](#)

Definition

Discontinuous data collection methods are those that capture only a sample of the behavior that is observed. During discrete trial teaching, discontinuous data collection may be used to record a

sample of the instructional trials such as the first trial or first few trials. When data are collected on the first instructional trial, the level of performance in the absence of immediately preceding learned trials or prompts is revealed. Discontinuous data collection may also be used to capture a sample of behavior during an observation by dividing the observation into predetermined duration intervals and recording either the occurrence or nonoccurrence of targeted behavior. Examples of this type of measurement include partial interval recording, whole interval recording, and momentary time sample. While continuous data collection may be more comprehensive, discontinuous data collection may be sufficient for decision-making and analysis if the sample represents a valid approximation of the true parameters of the behavior of interest.

Discourse Management

Sarita Austin

Unlocking Language, London, UK

Synonyms

[Conversational discourse](#); [Pragmatic language](#); [Topic management](#); [Turn-taking](#)

Definition

Discourse management refers to the ability to organize topics and turns and to repair any communication breakdowns during conversation. Carrying on a conversation involves the appropriate use and coordination of a variety of skills including: initiating and maintaining topics, using eye contact, taking turns, being polite, and observing and responding appropriately to nonverbal behaviors. During discourse, individuals must monitor their own contributions while taking into account the explicit and implicit responses, intentions, and knowledge of their conversational partner (s). The existing literature on language use and conversational skills in individuals with ASD indicates that the ability to contribute new information to topics introduced by others, shift topics appropriately, provide turns for others within conversation, take turns appropriately, and provide repairs for conversational breakdowns frequently present challenges to many individuals with ASD.

Discretionary Trust

Tobi Gilbert Juris

Quinnipiac University School of Law, Hamden, CT, USA

Discretionary Trust

A discretionary trust is a common method of estate planning whereby the creator of the trust (the *settlor*) transfers the assets to another (the *trustee*), who then has a duty to hold and manage the assets for the benefit of a third party (the *beneficiary*). If the trust is established by a living settlor, rather than through a will, the trust acts as a will substitute and the transferred estate avoids probate and some estate taxes.

The terms of a discretionary trust delegate power to the trustee to decide the “time, purpose and amount of all distributions” to one or more beneficiaries (POMS SI §01120.200.B.10). The trustee may be given complete authority over distributions that the trustee considers advisable. For example, a settlor might delegate absolute discretion upon a trustee in order to protect the long-term interests of a financially irresponsible beneficiary, or to establish a supplemental needs trust for lifetime support of an orphaned or disabled child. The purpose of such trusts may be to protect a spendthrift beneficiary from poor financial decisions; provide funds that “supplement, but not supplant, sources of income including SSI or other government benefits” (POMS SI §01120.200B.13); and shield the trust against invasion by the beneficiary, or the beneficiary’s general creditors. The trustee may only be compelled to distribute money from the trust under very restricted circumstances.

Alternatively, the settlor may limit the trustee’s discretion by directing that distributions be used for specific purposes. Often, such an arrangement is made to provide for the long-term care and support of an incompetent beneficiary. For instance, a trustee’s discretion is limited to

Discrete Versus Continuous

► Dimensional Versus Categorical Classification

distributing money for the “comfortable support, education, health and maintenance” of the beneficiary (Leslie and Sterk 2006). Support trusts are often used to provide care for a surviving spouse, or an incompetent or elderly adult.

Depending on the intent and objectives of the trust, creating a discretionary trust is an effective estate planning tool that may extend the life and availability of estate assets, while offering flexibility for the trustee to deal with unanticipated events. However, problems may arise such as a trustee’s breach of duty to manage the trust in “good faith,” or “in accordance with its terms and purposes,” or in the “interests of the beneficiaries” (Uniform Trust Code §801 *et. seq.*, 2005). This may be demonstrated when the trustee abuses the assigned discretionary power, and the beneficiary is not competent to address the breach. Therefore, one must carefully evaluate the goals of the settlor, the competence and trustworthiness of the trustee, and the long-term needs of the beneficiary in order to determine if a discretionary trust is the best estate planning option.

Disguised Mands

Patricio Erhard¹, Russell Lang² and Mandy Rispoli³

¹University of Texas at Austin, Austin, TX, USA

²Clinic for Autism Research Evaluation and Support, Texas State University, San Marcos, TX, USA

³Purdue University, West Lafayette, IN, USA

Definition

As described in the mand section of this encyclopedia, mands (a term derived from command, demand, counterdemand) are typically emitted from one person to another and yield a specific consequence (Skinner 1957, p. 53). For example, if a person said, “I want a cookie” to another person, and it led to the delivery of a cookie,

such exchange may be considered a mand. Unlike this example, when a mand does not directly state the specific intended consequence, the mand is called a disguised mand. Disguised mands are “responses that are under the control of an establishing operation (e.g., deprivation from cookies) and a discriminative stimulus (e.g., the presence of a listener) but the response does not specify the reinforcing consequence (e.g., access to cookies)” (Najdowski et al. 2017). In short, statements from one person to another, such as “I feel hot” or “I’m thirsty,” may be considered disguised mands because they do not directly indicate a specific desired consequence. Because disguised mands are indirect requests, initiating and responding to disguised mands may be challenging for individuals with social communication deficits, especially individuals with autism spectrum disorder (ASD; American Psychiatric Association 2013). Often, individuals with ASD have difficulty responding appropriately to sarcasm, metaphors, idioms, and other forms of language where the intended message is not directly stated (Najdowski et al. 2017). Because disguised mands are common parlance, responding in a socially acceptable manner is likely to improve social interactions but may require direct intervention. At the time of this publication, there are two studies that have conducted behavioral interventions to teach individuals with ASD to respond to disguised mands. Najdowski et al. (2017) used a combination of rule setting, role-play, and multiple exemplar training to teach three individuals with ASD to respond to disguised mands. First, the participants were provided with a rule that emphasized the importance of responding to people’s hints by helping them “because doing so makes them feel good and it will help [them] make and keep friends.” Then, the participants completed a role-play activity that involved responding to disguised mands, such as providing a pillow to an investigator that emitted the mand “I’m not very comfortable with my head just lying on the floor.” Last, the participants were provided with various examples and opportunities to respond to disguised mands, such as “I’m hot,” “I’m cold,” “I’m hungry,” etc. A replication and extension of Najdowski et al.’s study was

conducted by Erhard (2019) to include the training of nonvocal disguised mands as well. For example, in Erhard’s study, the participants were also taught to respond to disguised mands, such as when another person fans themselves with their hand when they are hot, wraps their arms around their body when they are cold, etc. Both studies indicated that the combined use of rule setting, role-play, and multiple exemplar training is an effective teaching strategy for teaching individuals with ASD to respond to various modalities of disguised mands. Both studies stressed the importance of future research to evaluate the effect that these teaching strategies have on the participant’s social environment. For instance, future studies could focus on teaching individuals to respond to disguised mands emitted by their peers or their parents.

Disparities Among African Americans with Autism

Wassim Hassan

Department of Neuroscience, Perelman School of Medicine at the University of Pennsylvania, Philadelphia, PA, USA

Historical Background

Autism spectrum disorder (ASD) is an umbrella term that includes a variety of specific neurodevelopmental impairments. These include Asperger syndrome, autistic disorder, and more. It is called a “spectrum” disorder because there is no single homogenous set of symptoms that present themselves across all cases. More accurately, ASD presents a series of symptoms that tend to manifest themselves at often vastly varying degrees from person to person. ASD is prevalent across all

racess, social classes, and geographic regions. According to the Centers for Disease Control and Prevention (CDC), common symptoms of ASD include problems with social, emotional, and communication behaviors. People with ASD tend to exhibit a strong affinity for routine and a severe distaste for sudden change. They also have trouble expressing their physical and emotional needs by way of conventional vectors of communication.

Throughout history, ASD has been severely mischaracterized and mistreated. Traditional approaches to ASD have simplified and misidentified the causes of ASD to simply bad parenting. This view persisted into the 1970s, and the subsequent developed approaches yielded more damage than harm. It was in the 1960s that the neurological nature of ASD was considered by Victor Lotter, and this was ultimately the spark that lit the convergence into a truly scientific approach to ASD (Lotter 1966). Lotter noticed a similar sociological manifestation between autism and other neurodevelopmental disorders and subsequently suggested that they shared a similar etiology. Researchers subsequently began to develop a category of distinct, but related disorders which they termed ASD.

Although there is significant research on ASD, understanding of the disorder as it relates to specific racial and ethnic groups is severely limited (Becerra et al. 2014). While there is a general consensus upon the similar prevalence of ASD across all demographic groups, there are other moving parts that affect other facets of ASD manifestation. Racial, ethnic, and class disparities in health literacy are well documented by various studies. One such study found that there remains a statistically significant disparity in health literacy between African Americans and Caucasians, and these disparities were more related to education and age rather than gender (Shea et al. 2004). These findings are devastating in a multifaceted manner, potentially affecting the outcome and treatment for nearly every prolific and rare medical problem across African American communities, as well as lifespans in potentially fatal scenarios. With this in mind, it is no surprise that the rate of disparity in excess death from chronic

diseases and other medical conditions between African Americans and Caucasians has increased from the 90s into the new millennium (Airhihenbuwa and Liburd 2006). These disparities are, no doubt, caused by a multitude of factors, including the socioeconomic marginalization of African American communities and the persistence of ghettos across America's larger cities. Studies have attributed an emotional causative pathway to certain pathophysiologies which play a hand in the rising health disparities (Carlson and Chamberlain 2004). At the most basic level, however, the problem begins with the failure to diagnose disorders.

Estimates indicate that ASD affects approximately 1 in 500 births every year. Studies have shown that rates of diagnosis for ASD between African American and Caucasian groups are not significantly different. There is a difference, however, in the stages at which ASD is diagnosed. Among African American groups, ASD tends to be diagnosed much later when compared to Caucasian groups (Gourdine et al. 2011). The implications of this are several, including later treatment, longer and more intensive intervention plans, increasing severity of untreated symptoms, and further psychological damage as a result of the patient's inability to be recognized as in need of extra care. This also poses the risk that the patient may never be diagnosed as autistic due to health illiteracy and lack of proper access to resources, which may result in significant difficulty later in life with the lack of proper accommodations in the educational system as well as discrimination in the work place without checks and balances by laws pertaining to disabled peoples.

Failure to diagnose ASD among other disorders has been attributed not only to socioeconomic factors such as literacy and access, but also to a higher prevalence of affinity towards religiosity and spiritual remedy. Various surveys and studies have indicated that significantly more African Americans identify as religious when compared with Caucasian populations. The ratio of religiosity can often present as 2:1 or more (Taylor et al. 1996). Misattributions of medical disorders to supernatural etiologies such as

demonic possession are not alien to the world of ASD. Religious scripture and preachers have often attributed mental disorders to demonic possession (Greydanus and Toledo-Pereyra 2012). Within African American communities, there are several major groups of churches that propagate supernatural access into the spiritual world as a way towards physical healing (Baer 1981). These churches belong to a wide array of denominations, including mainstream Baptists, Methodists, and Pentecostal churches among others. It is not surprising how influential religion remains as a factor in African Americans' health care perceptions and habits, given how prominent religion has been in African American history and cultural practice.

Overview of Current Research

By the late 1990s, Autism Spectrum Disorder (ASD) was diagnosed, on average, at 6 years of age, according to the findings of Dr. Patricia Howlin (Howlin and Moore 1997). Howlin's study spanned 1200 families with children having been diagnosed with ASD, or those in the process of receiving a diagnosis. The study did not emphasize ethnic disparities within the sample size, limiting the applicability of these findings to minority populations. The average age at which parents first became concerned with the child's mental development was 1.69 years of age (sd: 1.43, r: 0-18). Approximately 93% of parents had concerns by the time the child reached 3 years of age. A mere 10% were worried by 6 months of age, and in less than 3% of cases did the parents first become concerned after 5 years of age. Further, the average age at which parents first proceeded with professional assistance regarding their children's development was 2.3 years (sd: 1.94, r: 1 month to 38 years). Despite this, the average time that passed between parental concern about child development and the decision to seek professional help was 6-7 months, with over 23% of parents waiting up to 12 months.

Contemporarily, clinicians have successfully been able to detect ASD with reliable accuracy in children aged as young as 2-3 years old. The development of streamlined diagnostic

apparatuses such as the Autism Diagnostic Interview-Revised (ADI-R) and the Autism Diagnostic Observation Schedule-Generic (ADOS-G) have made this possible, but despite the technology, most children are not diagnosed before reaching 4 years of age (Couteur et al. 1989). The diagnosis tends to occur approximately 2 years after professional consultation is sought due to concern regarding the development of a child (Howlin and Moore 1997).

Unfortunately, many of these findings cannot be extended to African American populations, as the majority of recent research surrounding ASD has been almost exclusively limited to Caucasian populations. A study has found that African American patients that fall on the spectrum display more significant impediments in language development but typically yield the same degree of the other main symptoms of ASD (Cuccaro et al. 2007). Further analysis indicates that a higher social class marker is associated with greater chance of ASD (Bhasin and Schendel 2007). As it is understood that ASD occurs at a similar rate across all demographics, this statistic is indicative that a higher social class is more likely to result in a diagnosis of autism simply due to reasons of greater access to healthcare and higher health literacy. A large proportion of studies pertaining to non-Caucasian ASD patients focus heavily on the country of origin of the patients, which does not provide much in terms of etiology and disparities (Fombonne 2009). The CDC has reported that there is a higher frequency of ASD among Caucasian children as opposed to African American children in the majority of their studies. Additionally, Hispanic individuals with ASD were prevalent at a substantially lower rate when compared to Caucasian sample groups as well. A multisite case-control study of ASD yielded results that further indicate a lower rate of diagnosis among populations with less access to healthcare. Of a randomized population of 2768 children with ASD, approximately 33% of households had incomes below the United States median household income threshold (DiGuiseppi et al. 2016). Statistically, assuming that there is an equal proportion of ASD cases across all demographics, 50% of households should have

incomes below the United States median household income.

While it is thought that further studies will uncover factors that increase risk for ASD, the current corpus of research does not present much in that line of thought. Estimations of the frequency of ASD have been significantly increasing since the disorder was first characterized (Elsabbagh et al. 2012). Despite this, understanding of the etiological nature of ASD and potential factors that may increase the likelihood of its development is significantly limited (Newschaffer et al. 2007). The extent of recognition is that there is likely a deeply complex system of interplay between genetic, epigenetic, and environmental risk factors. Although studies are typically of low sample size along with a host of other clinical and infrastructural limitations, links between parental age and frequency of ASD have been suggested (Hultman et al. 2010). Despite these findings, the baseline operational fulcrum of thought is that ASD tends to occur at similar proportions across all demographics. Until conclusive studies are produced otherwise, attention must be paid to the disparities in the rate of diagnosis and onset of treatment between African American and Caucasian populations.

Future Directions

While it is recognized that individuals diagnosed with ASD are found in all regions, ethnic groups, cultural backgrounds, and socioeconomic levels, there has been inadequate attention given to ethnic disparities. While it is conceivable that unknown risk factors factor into the etiology of ASD and potentially present differences in the prevalence of the disorder among various populations, there is currently more work to be done prior to fixating research upon this facet of study. It is imperative that studies which properly measure the prevalence of ASD are fortified by a more accurate sampling, and such an accurate sampling is achievable by way of establishing a more reliable infrastructural pathway towards the diagnosis and treatment of ASD among African Americans and other minority populations.

There is no doubt that there exists a variety of confounding factors in the statistics regarding the proportionality of African American individuals with ASD. Many of these factors are cultural, while others are infrastructural. To overcome the infrastructural barriers towards diagnosing African American individuals with ASD, government policies must pave the road towards more accessible pathways to proper treatment. This may be manifested as an increase in resources focused on providing pediatric healthcare in low income urban areas and providing social workers trained to identify such disorders at an early age. Not only should these social workers be available to minorities living in low-income neighborhoods, but it is important that they also be financially accessible – perhaps by way of government subsidization. Disparities in the academic performance of children with ASD exist across ethnic lines, and this is a reality that may be dealt with by way of policy.

Confounding factors to do with cultural realities among African American populations should be addressed by way of social initiatives towards health literacy. So as to curb perception of the undermining of institutions such as churches that tend to emphasize alternative healing attempts, NGOs, and government initiatives should go about establishing relationships with these institutions to provide adequate health literacy. Health literacy workshops, blood drives, and health screenings are not unheard of in such institutions, and this is a potentially effective way to begin dampening these confounding variables.

More comprehensive study of the sociocultural influences that may delay and even altogether curb the effort to diagnose and identify ASD among African American populations are necessary. Studies into the magnitude of effect presented by disparities in health literacy and access to health are an excellent first step towards accomplishing this goal. The critical teleology of these studies, however, should be to generate accurate statistics to form the basis of research into the etiology of ASD. Of course, the aforementioned sociocultural research would assist in narrowing down proposed genetic, epigenetic, and lifestyle factors in the study of ASD etiology. Diagnostic techniques based upon behavior and

cognitive development may only go so far in the study of ASD. In the case of discovering a genetic etiology, ASD could potentially be pinpointed prior to birth, allowing for immediate medical attention and in increased threshold for development. A more holistic fundamentally focused approach will yield the most accurate data.

Dispute Resolution Procedures

Jonathan Sliva
Quinnipiac University School of Law, Hamden,
CT, USA

Definition

A dispute resolution procedure is a method of resolving a conflict between parties. Historically,

dispute resolution was judicial in nature; however, in recent years the number of disputes resulting in trial has decreased significantly due in part to the advent of alternative dispute resolution (ADR) procedures such as arbitration, mediation, and negotiation. Today, most references to a dispute resolution procedure are to these alternatives to litigation (Yarn 1999, p. 154). These methods of dispute resolution along with other types of ADR may be utilized by parties trying to minimize costs and avoid the adversarial nature of litigation.

Types of Alternative Dispute Resolution Procedures

Modern alternative dispute resolution procedures were developed primarily as a response to the rising levels of litigation in the United States throughout the twentieth century. In the mid-1970s, Harvard Professor Frank Sander articulated his vision of a system where, instead of leading directly to litigation, disputes could be directed to various alternative methods to resolve the dispute without resorting to a trial. He described this multifaceted system of the judiciary working alongside other forms of conflict resolution as the “multidoor” courthouse. (Menkel-Meadow 2005, p. 19). The implementation of such alternatives to litigation has greatly reduced the number of cases going to trial even as the number of complaints filed in courthouses has greatly increased (Stipnowich 2004, p. 844).

Arbitration

Arbitration is a dispute resolution process in which the disputing parties present their cases to a third party intermediary who makes what is usually a binding decision for the parties. Arbitration is generally not as formal as in-court adjudication, and the procedural rules can be structured to meet the necessities of the particular situation. As in court-based adjudication, the outcome of an arbitration proceeding will typically result in a clear winner and loser. Although the arbitrator may recommend a solution that clearly benefits

both parties, arbitrators are not expected to develop ideas for meeting the interests of both sides or to help the parties see areas of agreement and reconciliation.

Mediation

Mediation is a process in which the parties attempt to resolve a conflict with the assistance of a neutral third party (mediator) (Yarn 1999, p. 272). Mediation is similar to negotiation in that the parties to the dispute are in control. However, to assist the process of negotiation, the mediator is present to help reach a mutually agreeable solution to their differences. Although ultimate control and decision-making authority remain with the parties, the mediator has significant power throughout the process to direct the negotiations, identify areas of agreement, and encourage the parties to accept concessions (Goldberg et al. 2007, p. 107).

Negotiation

Negotiation is a process where the parties, with the aid of a mediator, attempt to come to a mutually acceptable agreement about issues on which they disagree (Nieuwmeijer 1988, p. 9). The parties use bargaining and open communication to reach a consensus over their outstanding issues. Negotiation works best in situations where all parties involved in the process have a mutual interest in resolving their dispute and are willing to each make concessions in order to reach an acceptable resolution.

Distributed Practice

Rebecca Munday
The Center for Children with Special Needs,
Glastonbury, CT, USA

Definition

Distributed practice is a technique commonly used with students who are learning material or studying for a test. It involves the student creating a schedule of study sessions that are short in duration. Distributed practice can be contrasted to massed practice or cramming, where the student spends fewer studying sessions but for longer periods of time. This technique has proven to be beneficial for maintaining newly learned skills. Distributed practice aids students in prioritizing learning material.

Dizygotic (DZ) Twins

Paul El-Fishawy
 State Laboratory, Child Study Center, Yale
 University, New Haven, CT, USA

Synonyms

[Fraternal twins](#)

Definition

Twins are two individuals who are the result of the same pregnancy. Dizygotic twins are nonidentical or fraternal twins. This is in contrast to identical or monozygotic twins. Unlike the case in monozygotic twins, the genetic information or deoxyribonucleic acid (DNA) carried by each of

the individual twins in a pair of dizygotic twins is different. This genetic information in the form of DNA is the material inherited from each of the parents that contains all the instructions for the creation and subsequent operation of an individual. Errors in this genetic information can lead directly to disease or make individuals more susceptible to disease.

In singleton pregnancies, a sperm from the father fuses with an egg from the mother, and together, they form a single cell called a zygote, the earliest stage of an embryo. In the case of dizygotic twins, two separate eggs in the mother are released at one time. Each of these is then fertilized by a separate sperm from the father and forms a distinct zygote and embryo. Since each sperm and egg carry distinct genetic material, each of the two embryos will, thus, carry distinct genetic material. On average, dizygotic twins' genetic material is only about 50% identical, as compared to 100% for monozygotic twins. Since each dizygotic twin carries distinct genetic material, his or her physical appearance will be distinct. Dizygotic twins may be of the same sex. However, they might also be of different sexes.

Monozygotic twins, in contrast, form as follows. A sperm from the father fuses with an egg from the mother and initially forms a single zygote. Further cell divisions occur during embryonic development. At an early point in this development, the embryo in the case of monozygotic twins splits into two separate embryos, the cells of each having originated from the initial zygote. Each of these embryos goes on to develop into a separate and complete individual. Since each originated from the same initial cell, each individual is identical in his or her genetic composition. Barring rare occurrences (see ► [Monozygotic \(MZ\) Twins](#)), since monozygotic twins share the same genetic material, their physical appearance will be identical, and they will be of the same sex.

Dizygotic twinning is more common than monozygotic twinning. Dizygotic twins comprise approximately two thirds of all twins. Monozygotic twins comprise one third. While the rate of monozygotic twinning in pregnancies that are

unassisted by fertility treatments is relatively stable across world populations at a rate of approximately 4 in every 1,000 live births, there is evidence that the rate of dizygotic twinning in the absence of fertility treatments varies from population to population. Studies estimate that dizygotic twinning rates are the lowest in East Asian countries fewer than 8 per 1,000 live births. Dizygotic twinning rates are intermediate in Europe, the United States, and India with a rate of approximately 9–16 per 1,000 births. They are highest in some African countries where they can be 18 or greater per 1,000 births.

The rate of both monozygotic and dizygotic twins has increased worldwide since the 1970s. It is thought that the majority of the increase has resulted from the increase in dizygotic twins born as a result of fertility treatments. Twin pregnancies of either type increase pregnancy risk and especially the risk of preterm delivery and low birth weight. Approximately 51% of twins are born preterm compared to 9.4% of singletons.

Domenic Cicchetti

Roald A. Øien

Department of Psychology/Department of Education, UIT – The Arctic University of Norway, University of Tromsø, Tromsø, Norway
Yale Child Study Center, Yale Autism Program, Yale University School of Medicine, New Haven, CT, USA

Biography

Dr. Domenic Vincent Cicchetti, PhD (1937–2019), was a biostatistician most notably known for the development of the Vineland Adaptive Behavior Scales (VABS) together with his late wife Sara Sparrow, a renowned clinical psychologist at the Yale Child Study Center.

Dr. Cicchetti obtained his BA, MA, and PhD between 1955 and 1965 in social psychology and

biostatistics at the University of Connecticut. He later obtained positions as a Senior Research Scientist at the Yale School of Medicine in the Child Study Center and Department of Psychiatry and School of Epidemiology and Public Health. He was an adjunct professor in the Department of Psychology at the University of Windsor in Ontario, Canada, and served as a Visiting Professor in the Division of Neuroscience & Psychological Medicine, Department of Public Mental Health, Imperial College of Science, Technology, and Medicine, St. Mary's Campus, London, England (Øien et al. 2019).

As mentioned, Dr. Cicchetti was most notably known for his work together with his wife Sara Sparrow in the development of the VABS and its later editions (Sparrow et al. 2005). But in addition to the development of the Vineland, Dr. Cicchetti authored or co-authored over 200 research publications in behavioral and biomedical research, computer science, and biostatistics that have been widely cited and been essential to the field of developmental psychology and disabilities. The *Vineland* would become the most widely used adaptive behavior assessment instrument in the world. For the development and publication of the *Vineland*, Dr. Cicchetti received the first Connecticut Psychological Association's Award for Distinguished Effort by a Connecticut Psychologist in 1984 together with his wife Sara Sparrow. Dom was a fellow in Division 5 of the American Statistical Association. Dr. Cicchetti was widely known for his development of methods to assess the psychometric properties and work on statistical methodologies in regard to validity and reliability. Dr. Cicchetti has, per May 2020, still scientific contributions in the peer review process.

To summarize, Dr. Domenic Vincent Cicchetti was a prolific scientist in the field of autism and related disabilities, developing instruments and methods that ultimately have led to the fact that an enormous amount of individuals globally have received services for their disability. Dr. Cicchetti also contributed massively to the understanding of statistical versus clinical meaningful results (Nordahl-hansen et al. 2018). Dr. Cicchetti deceased on June 30, 2019.

Dominance, Cerebral

Kevin A. Pelphrey Harris
Child Study Center, Yale University School of Medicine, New Haven, CT, USA

Synonyms

Hemispheric dominance; Hemispheric lateralization; Hemispheric specialization

Definition

Cerebral dominance refers to the dominance of one cerebral hemisphere (commonly referred to as the left or right side of the brain) over the other in the control of particular cerebral functions. After decades of study in the fields of behavioral neurology, systems neuroscience, neuroimaging, and neuropsychology, it is clear that each hemisphere of the brain is dominant for specific behavioral and cognitive functions. For example, in most right-handed individuals, portions of the right hemisphere temporal lobe are specialized

for processing faces, and similar regions of the left hemisphere temporal lobe are specialized for processing letters. Similarly, in approximately 95% of right-handers and 65% of left-handers, the left side of the brain is dominant for language.

Synonyms

[Aricept](#); [DONEP](#)

Definition

Donepezil is a central nervous system selective, reversible acetylcholinesterase inhibitor. Acetylcholinesterase is an enzyme that degrades acetylcholine (ACh), a neurotransmitter involved in the

pathogenesis of autism-related behavioral deficits such as inattention, decreased cognitive flexibility, lack of social and communication abilities, and increased stereotypical behaviors. Thus, donepezil serves to increase levels and action duration of ACh in the hopes of reversing abnormal phenotypes caused by deficits in ACh production and/or receptor function. Currently, donepezil is most widely used in the treatment of Alzheimer's disease. Its effectiveness has also been demonstrated in vascular and Parkinson's-associated dementia. In ASD, donepezil has demonstrated improvements mainly in expressive language but also in terms of general behavior, i.e., irritability, hyperactivity, eye contact, and inappropriate speech. Evidence also suggests donepezil's potential use in improving REM sleep duration in ASD patients. However, with all these observations further, substantial, larger-scale validation is required.

Definition

Dopamine is a neurotransmitter that is implicated in the pathophysiology of many psychiatric and neurologic disorders. Its most notable psychiatric role is in the pathophysiology of psychosis and schizophrenia, particularly the presence of hallucinations and delusions. However, among a complicated network of neural pathways, dopamine is also believed to influence mood states, anxiety, cognition, and the presence of repetitive symptoms experienced in conditions like autism spectrum disorders (ASD), Tourette's disorder, and obsessive-compulsive disorder. For these reasons, dopamine is the target of research attempting to uncover etiologies and treatments for such diseases. Understanding dopamine's relationship to ASD may offer much insight into the pathophysiology of its symptoms.

Dopamine is synthesized in specialized neurons using the amino acid precursor tyrosine (Stahl 2008). Tyrosine is first pumped from the extracellular space into dopaminergic neurons by a tyrosine transporter. Within the neuron, tyrosine then passes through the rate-limiting enzyme tyrosine hydroxylase, followed by the enzyme dopa decarboxylase, to become dopamine. (Dopamine can also be converted to the neurotransmitter norepinephrine via the enzyme dopamine beta-hydroxylase.) Dopamine is packaged into vesicles by a vesicular monoamine transporter (VMAT2) for storage until later use. When a neuron receives the

appropriate signal, dopamine is released from synaptic vesicles to travel across the cleft between the presynaptic and postsynaptic axon terminals. Once in the cleft, dopamine is free to attach to dopamine receptors on the postsynaptic axon terminal. It can also be taken up by dopamine transporters in the presynaptic axon terminal to be repackaged for later use or degraded. One of the most notable receptors is the dopamine-2 (D₂) receptor, which is located on postsynaptic axon terminals, presynaptic axon terminals, and somatodendritic areas. When dopamine attaches to D₂ receptors on the presynaptic axon terminal or somatodendritic areas, D₂ receptors provide negative feedback that slows or further prevents the release of dopamine from the presynaptic terminal. Excess dopamine is degraded within the neuron by the enzymes monoamine oxidase (MAO)-A or MAO-B and outside the neuron by the enzyme catechol-O-methyltransferase (COMT). In some areas in the brain, such as the frontal cortex, there are fewer dopamine transporters to take up excess dopamine remaining in the cleft, so these alternative routes of degradation function to regulate dopamine concentration.

There are five key dopamine pathways in the brain. The first is the mesolimbic pathway, which projects from the dopaminergic cell bodies of the ventral tegmental area of the brainstem to the nucleus accumbens in the ventral striatum. Increased dopamine activity in this pathway is thought to generate psychosis, also known as the "positive symptoms" of schizophrenia, which include hallucinations and delusions. Stimulant drugs, like amphetamine and cocaine, produce increased dopaminergic activity and subsequent psychotic symptoms, whereas first- and second-generation antipsychotic medications, which antagonize dopamine in this pathway, cause reduced psychotic symptoms. The mesolimbic pathway is also known to regulate emotions, motivation, pleasure, and reward. Dysfunction in this area may result in symptoms such as avolition and anhedonia, accounting for some of the "negative symptoms" of schizophrenia. The second pathway is the mesocortical pathway, which projects from the dopaminergic cell bodies of the ventral

tegmental area to the prefrontal cortex. Branches from this pathway are believed to regulate cognition and executive function, as well as emotion and affect. Unlike the mesolimbic pathway, where an excess of dopamine is hypothesized to produce symptoms of psychosis, a deficit of dopamine in the mesocortical pathway is thought to cause more negative symptoms observed in schizophrenia, such as flat affect, reduced cognition, and impaired executive function. The model of increased or decreased dopaminergic activity in different pathways is hypothetical and is likely an oversimplification of a more complex system yet to be understood. The third pathway is the nigrostriatal pathway, which projects from the dopaminergic cell bodies in the brainstem substantia nigra to the basal ganglia or striatum. This area regulates motor movements and is part of the extrapyramidal nervous system. Hypoactivity of dopamine in this pathway produces parkinsonian symptoms of rigidity, akinesia or bradykinesia, and tremor. Hypoactivity in the basal ganglia specifically can result in dystonia or akathisia. Hyperactivity of dopamine in this pathway results in hyperkinetic movements, such as tics, chorea, and dyskinesia. Longer term blockade of the D₂ receptors via antipsychotics can produce a hyperkinetic disorder known as tardive dyskinesia. The fourth pathway is the tuberoinfundibular pathway, which projects from the hypothalamus to the anterior pituitary. Dopamine typically inhibits prolactin, a hormone that results in lactation. When dopaminergic activity is blocked in this pathway, prolactin levels rise as it is no longer inhibited. Elevated prolactin can cause galactorrhea (breast secretions), amenorrhea (loss of ovulation and menstruation), and possibly sexual side effects. This can occur with the use of antipsychotic medication, which blocks D₂ receptors. The fifth pathway is the lesser-known thalamic dopamine pathway, which innervates the thalamus. It is thought to originate in multiple sites, including the periaqueductal gray matter, ventral mesencephalon, hypothalamic nuclei, and lateral parabrachial nucleus. The function of this pathway may involve regulation of sleep and arousal.

Historical Background

In the late 1950s, a Swedish pharmacologist named Arvid Carlsson was the first person to discover dopamine as a distinct neurotransmitter, and in the year 2000, he won the shared Nobel Prize in Physiology and Medicine for this very significant contribution. As outlined in Abbott's article in *Nature* (2007), this monumental discovery occurred while experimenting with reserpine, the first antipsychotic to be used in the treatment of schizophrenia. Treatment with reserpine was observed to cause a catatonic state in experimental rabbits, but the mechanism by which this happened was unknown. Using a spectrophotofluorimeter, a machine used to measure the amount of neurotransmitter synthesized from fluorescently tagged precursors, Dr. Carlsson determined that reserpine somehow drained stores of brain neurotransmitters. Because the known neurotransmitters serotonin and norepinephrine were not able to cross the blood-brain barrier, Dr. Carlsson hypothesized that their precursors could be injected and cross over the blood-brain barrier to be converted to the needed neurotransmitters, hopefully restoring movement. He extracted serotonin and norepinephrine precursors, one of which was l-dopa (levodopa), and injected them into the catatonic rabbits. l-dopa restored movement in the animals, and Dr. Carlsson determined dopamine to be a separate neurotransmitter while examining the rabbits' postmortem brains.

With the help of his graduate students, Dr. Carlsson went on to discover dopamine concentrated in areas of the brain associated with movement, like the basal ganglia. Given the similarities between reserpine's side effects and Parkinson's disease, he hypothesized that the disease must be caused by a deficiency of dopamine. He brought these ideas to various symposia but received a mixed reception; the favored thinking at that time was that nerve conduction in the brain occurred via electrical impulses, with little emphasis on chemical transmission. Slowly, others began uncovering similar results, publishing studies showing an absence of dopamine in the basal ganglia in patients with Parkinson's

disease (Ehringer and Hornykiewicz 1960) and that healthy basal ganglia neurons contain high levels of dopamine (Birkmayer and Hornykiewicz 1961; Dahlstrom and Fuxe 1964). The drug is not without imperfection, and unwanted side effects such as nausea and emesis can occur. At times, the drug can lose its therapeutic effect in some patients. Nonetheless, l-dopa continues to be the first-line treatment for Parkinson's disease. It also likely garnered increased public awareness after being featured in the 1973 book *Awakenings* by British neurologist Oliver Sacks. This memoir recounts Dr. Sacks' use of l-dopa in 1969 to treat patients with catatonia who survived the 1917–1928 outbreak of *encephalitis lethargica*, otherwise known as sleeping sickness. The book was transformed into a 1990 film with the same name starring American actors Robin Williams and Robert De Niro. In 1961, l-dopa was injected into the first Parkinson's patients with dramatic effect, providing relief for their rigidity and immobility.

Not long after the discovery of dopamine's relationship to Parkinson's disease, neurologists observed that treatment with l-dopa resulted in psychosis, leading to the discovery that the pathophysiology of schizophrenia may be related to dopamine. The observation that antipsychotic drugs caused movement disorders similar to that observed in Parkinson's disease leads Dr. Carlsson to reason that antipsychotics blocked dopamine receptors, resulting in a feedback mechanism by which neurons released more compensatory dopamine. These conclusions have led Dr. Carlsson to become a pivotal figure in the discovery of dopamine as a distinct neurotransmitter, as well as someone who uncovered fundamental mechanisms in neurotransmission that continue to be employed today.

With time, neural pathways controlling dopamine were thought to influence motivation and reward, exemplified by the tendency of patients treated with l-dopa to gamble excessively. Research into addiction and drugs of abuse has also implicated brain regions and neural pathways primarily governed by dopamine. Dopamine's widespread effect in the brain has led autism researchers to investigate it in the

pathophysiology of ASD. The relationship between dopamine and ASD is explored in the “Current Knowledge” section.

Current Knowledge

Due to its extensive innervation of the brain, dopamine has been hypothesized to be involved in the pathophysiology of ASD. According to Baskerville and Douglas (2010), neurologic behavioral disorders caused by profound disruption of the key dopaminergic pathways in the brain are known to adversely affect prosocial behavior. These pathways likely involve complex interactions with multiple other neurotransmitters and neuropeptides, and it is hypothesized that dysfunctional interactions result in the aberrant social behavior observed in ASD. One of the proposed interactions is between dopamine and oxytocin, a neuropeptide with physiologic and behavioral influences. Oxytocin is an endocrine hormone that regulates parturition and milk ejection, but is also involved in regulating social behaviors such as social bonding, parental behavior, and sexual behavior (Lee et al. 2009). It is also thought to regulate nonsocial behaviors such as stress, anxiety, and aggression, which all appear in ASD, and has been thought to be influenced by dopamine pathways. Given their shared roles, dopamine and oxytocin are hypothesized to jointly contribute to aberrant social behaviors, anxiety, and aggression in ASD. The results of studies linking oxytocin to the pathophysiology of ASD have been mixed, however, but treatments involving intranasal oxytocin have resulted in improvements in communication and secure relationship attachment (Heinrichs et al. 2009; Kosfeld et al. 2005). Unfortunately, revealing a definitive, symbiotic relationship between oxytocin and dopamine has yet to occur, but research in this area continues. There has been stronger evidence linking dopamine dysfunction with autism-like disorders, particularly involving the dopamine transporter and D₄ receptor genes (Baskerville and Douglas 2010). Nakamura et al. (2010) used positron emission tomography (PET) to study the binding of dopamine and serotonin

transporters in the brains of autistic male adults compared to age- and IQ-matched controls. They found that dopamine transporter binding was significantly higher in the orbitofrontal cortex of the autistic individuals and that this was inversely correlated with serotonin binding, which was lower throughout the brain of autistic individuals. They concluded that dysfunction in dopamine and serotonin systems likely contributes to the pathophysiology of autism.

Research has attempted to link symptoms of ASD to specific genetic polymorphisms and neuroanatomical regions of the brain. For example, the presence of repetitive, stereotyped behaviors in ASD has been associated with the basal ganglia and frontal lobe circuitry (Langen et al. 2011), which is believed to be regulated by the dopamine system. Housed in the basal ganglia is the caudate nucleus, a brain region associated with behavioral rigidity. The caudate nucleus has been found to be enlarged in ASD, representing one of the best replicated neuroimaging findings in ASD research (Langen et al. 2009). The basal ganglia, particularly the caudate nucleus, exhibit high expression of the dopamine-3 receptor gene (DRD3), a gene that appears to be associated with ASD. Genetic studies have revealed an association between the SNP (single nucleotide polymorphism) rs16777 on DRD3 and ASD (de Krom et al. 2009). This polymorphism is also related to risperidone-induced extrapyramidal symptoms (Gasso et al. 2009), which is significant because risperidone and aripiprazole (a partial agonist at the D₂ receptor) are the only FDA-approved drugs for the treatment of symptoms associated with ASD (Staal et al. 2011). The DRD3 receptor site is also an action site for atypical antipsychotic drugs, and another of its polymorphisms is a predictor for improvement with risperidone therapy (Correia et al. 2010). All of this data supports a positive association between the presence of the DRD3 gene and ASD; however, a small study performed by Staal et al. (2011) revealed that the presence of SNP rs16777 on DRD3 paradoxically decreased the risk for “insistence on sameness,” a form of stereotyped behavior observed in ASD. Given the breadth of findings, some which are

conflicting, there is a need for continued research into DRD3 and its relationship to symptoms of ASD.

Other genetic biomarkers of interest include dopamine transporter gene (DAT1) and dopamine D4 receptor gene (DRD4). In a study by Gadow et al. (2010), the DAT1 and DRD4 genotypes approached significance for teachers’ ratings of oppositional behavior and mothers’ ratings of tics. The researchers proposed that variation in the alleles for DRD4 may serve as biomarkers predicting challenging behaviors in children with ASD, but the study was small and would require replication with larger samples.

Despite these attempts at localizing specific genes implicated in the pathophysiology of autism, some research indicates that it may not be so simple. A study genotyping 28 SNPs of 14 prominent dopamine pathway candidate genes concluded that the evidence was not strong in favor of linkage or association to any specific gene or combination of genes within the pathway (Anderson et al. 2008). The role of genes within the dopamine pathway, if any, was considered mild to moderate in the pathogenesis of autism.

Inattention and hyperactivity, symptoms that commonly occur in autism, also appear to result from dysfunction of the dopamine system. Gadow et al. (2008) found that a variable number tandem repeat (VNTR) in a region of the dopamine transporter gene (DAT1, SLC6A3) was associated with the severity of ADHD, anxiety, and tics in children with ASD.

The association between dopamine and autism is also evident via the observed effects of antipsychotics medication on the treatment of irritability in ASD. Approximately 30% of children and adolescents with ASD suffer from moderate-to-severe irritability (Lecavalier 2006). Irritability can include aggressive acts towards the self (self-injurious behavior) or others and severe tantrums. Currently, the most effective drugs used to treat symptoms of irritability are the antipsychotics, which are believed to antagonize postsynaptic D₂ receptors in the brain, although some may also have serotonin receptor antagonism. At present, there are only two atypical antipsychotics

that are FDA-approved for the treatment of irritability in autistic disorder: risperidone (Risperdal) and aripiprazole (Abilify). Risperidone is FDA-approved for the treatment of irritability in patients with autistic disorder aged 5–16 years, whereas aripiprazole is approved for the treatment of patients with autistic disorder aged 6–17 years. Risperidone is a potent D_2 antagonist, whereas aripiprazole has partial D_2 receptor agonists, meaning it detaches from the D_2 receptor more readily than risperidone and typical antipsychotics. These traits may contribute to these drugs' relative success in managing symptoms observed in ASD. Other antipsychotics that have been studied include the “typicals,” such as haloperidol, pimozide, chlorpromazine, trifluoperazine, thiothixene, trifluoperidol, fluphenazine, and molindone. Other atypical antipsychotics include clozapine, olanzapine, quetiapine, and ziprasidone. In addition to irritability, some studies have noted reductions in other symptom domains such as repetitive behavior and inattention, hyperactivity, and impulsivity. However, the direct relationship between dopamine and these symptom outcomes is not always apparent, so future research is needed to explicate this.

Future Directions

Future directions for research into the relationship between dopamine and autism will likely involve genetic studies, neuroendocrine research, neuroimaging, and pharmacologic treatment development. Genetic research has focused on identifying polymorphisms that may or may not be associated with symptoms of ASD. This type of research has yielded mixed results but will likely continue to examine the association between ASD and dopamine receptor genes like *DRD3* and *DRD4*. Attempting to link dopamine and oxytocin has also not yielded strong results, but their shared roles with regard to social behavior, stress, anxiety, and aggression will likely spur continued research attempting to find an association. Given the consistent finding of an enlarged caudate nucleus in patients with ASD, a dopamine-rich

area of the brain, neuroimaging may continue to yield useful information about other brain regions that utilize dopamine and how they relate to symptoms of ASD. It may also reveal more about dopamine binding in such areas. Lastly, new pharmacological treatments for symptoms of ASD should be investigated via randomized, double-blind, placebo-controlled studies to ensure a variety of safe and efficacious treatments are available to patients. The atypical antipsychotic paliperidone, which is the active metabolite of risperidone, is an evident choice since risperidone has shown efficacy in treating children and adolescents with autistic disorder (Stigler et al. 2010).

Medicine, New Haven, CT, USA

Definition

Dorsomedial frontal cortex (DMFC) is a region of the prefrontal cortex associated with interpreting social situations, specifically the ability to comprehend other's thoughts and intentions known as Theory of Mind. Functional imaging studies have identified reduced activity in DMFC during social decision tasks in ASD patients compared to neurotypical controls. Neuroanatomical studies have identified changes in organization of neurons in the DMFC in ASD patients, specifically Brodmann's area 9.

Definition

The double empathy problem (DEP) refers to a “disjuncture in reciprocity between two differently disposed social actors” who hold different norms and expectations of each other, such as is common in autistic to non-autistic social interactions (Milton 2012, p. 884). With

different dispositional outlooks and personal conceptual understandings, interactions involving autistic and non-autistic people are susceptible to frequent misunderstandings. It is a “double problem” as both people experience it, and so it is not a singular problem located in any one person. However, “the disjuncture may be more severe for the non-autistic disposition as it is experienced as unusual, while for the ‘autistic person’ it is a common experience” (Milton 2012, p. 885).

In principal, the DEP becomes more marked the wider the disjuncture in dispositional perceptions of what constitutes the social context. It is suggested that “social subtext is never fully given as a set of *a priori* circumstances, but is actively constructed by social agents” (Milton 2012, p. 884). Thus, as interactions unfold, an initial gap in mutual understanding due to a dispositional difference can readily become a critical gap in mutual understanding which potentially terminates the interaction.

The explanatory scope of the double empathy problem is broad because it considers both individual outlooks of multiple social actors and the social context in which interactions takes place, such as cultural norms and stereotypes. Features of the double empathy problem that are characteristic of misunderstandings for non-autistic social actors include difficulties in reading autistic facial expressions and interpreting autistic perspectives, overgeneralizing attribution of blame, reduced tendency to critically reflect on one’s own role in contributing to misunderstandings, and underestimating autistic social ability because it may manifest unpredictably. Features of the double empathy problem experienced by autistic social actors include increased anxiety about interactional outcomes, increased frustration, and lower self-esteem, which in turn can have a potentially cascading effect on future mental health, economic prospects, and accessing supports and services.

The difficulty autistic people have in understanding non-autistic people has been extensively researched, although arguably not adequately from an autistic point of view (Milton and Bracher 2013). We therefore focus on research which

highlights the relatively ignored difficulties that non-autistic people have in understanding autistic perspectives.

Historical Background

The DEP theory originated from autistic scholar Damian Milton through discussions when advising parents in the late 2000s. Prior to diagnosis of his son and himself as autistic, Milton had referred to the DEP concept as “conditioned relativism” and “dispositional diversity” in the 1990s (Milton 2014a). Upon learning of his diagnosis, Milton began to explore autism theory including Theory of Mind. The DEP was Milton’s reinterpretation of ToM which re-situated perspective-taking and empathy as a two-way interactional process. It first appeared as a concept in conference presentations from 2010 and was first published in 2012 (Milton 2012). The theory was soon developed further looking at the concept of “interactional expertise” (Collins and Evans 2007; Milton 2014b) using Iris Marion-Young’s concept of “Asymmetrical Symmetry” (Milton 2016a).

The DEP has a number of theoretical antecedents reaching back to George Herbert Mead and his conceptualization of a “social act” (Mead 1934). For Mead social interaction did not comprise of functionally separate stimulus and response elements, because the categorization of such elements depends on one’s position within the social field. Instead a reciprocal relationship exists between stimulus and response whereby the response of one person is simultaneously the stimulus for another person. In this manner, people coregulate each other’s behavior through interaction. A two-way understanding of human social relations wherein people have the power to mutually reinforce each other’s behavior is the foundation of sociological works by Erving Goffman (1958) and Harold Garfinkel (1964) and underpins later work on “intersubjectivity” (Schegloff 1992).

The DEP shares commonalities with other theories explaining autistic social interaction. Ian Hacking’s research on “the looping effect”

explores the two-way effects of empathy that exists between society and individuals (Hacking 1995), wherein knowledge about an autistic diagnosis shapes the way autistic people behave and how others orientate to them, in turn “looping back” to reinforce societal expectations. Similarities can also be found in the work of Beardon (2017) in regard to what he refers to as “cross-neurological theory of mind,” and in the work of Chown (2014) who examined the double empathy problem through the use of Wittgenstein’s criteriological view of mind. Jaswal and Akhtar (2019) have argued that some influential accounts of autism may be based on unfavorable interpretation of autistic social motivation by non-autistic scientists, and that a more accurate and humane approach would consist of giving greater emphasis to autistic testimony. Bolis et al. (2017) have also examined the DEP in terms of a “dialectal misattunement hypothesis” which relates to disruptions in the dynamic and reciprocal nature of interactions across time, resulting in prediction errors and divergent interaction styles.

Current Knowledge

A growing body of experimental research is consistent with the notion that non-autistic people perceive autistic people differently and are prone to misperceiving autistic people.

Studies of Mindreading

Several studies have investigated whether non-autistic people find facial expressions of autistic people more difficult to read than those of non-autistic people. The majority of these studies asked groups of autistic and non-autistic participants to pose a series of facial expressions of emotion. Photos of these expressions were then shown to a separate group of raters who were blind to the diagnostic status of the participants and were asked to judge the emotion. Some studies have found the expressions of autistic participants were recognized more poorly than those posed by non-autistic comparison participants (Macdonald et al. 1989; Brewer et al.

2016), although others have found little difference (Volker et al. 2009).

Some studies have attempted to capture emotional expressions in more naturalistic ways, closer to the circumstances under which they may be observed in everyday life. Grossman et al. (2013) used a story retelling task and found that non-autistic adults were equally able to use facial expressions to identify the emotional content of a story told by autistic and non-autistic participants. Faso et al. (2015) elicited emotions in autistic and non-autistic participants by narrating autobiographical memories to them, finding that the facial expressions of autistic participants were recognized just as accurately as those of non-autistic participants, and in fact, anger was recognized more accurately for autistic participants.

Non-autistic people may also have difficulty interpreting other aspects of autistic people's behavior. Sheppard et al. (2016) investigated non-autistic participants' ability to interpret the behavioral reactions of autistic people in naturalistic social interactions. Autistic and non-autistic participants were covertly filmed reacting to a seemingly incidental but actually scripted aspect of the researcher's behavior. While briefing the participant, she either told them a joke, paid them some compliments, told them about the difficult day she was having, or kept them waiting while doing irrelevant activities. Non-autistic participants who viewed the recorded videos were less able to guess which event the video participant had experienced for autistic than non-autistic participants, apart from for reactions to the joke. Edey et al. (2016) asked autistic and non-autistic participants to manipulate two triangles to create animations depicting mental state interactions such as "coaxing" or "mocking." Non-autistic observers who viewed the animations were better at identifying the mental state depicted for animations created by other non-autistic participants than autistic participants.

In summary, research in this area suggests that while non-autistic people may sometimes be able to identify facial expressions of autistic people, they have difficulty making sense of autistic people's behavior in context which might negatively

impact on social interactions between autistic and non-autistic people.

Studies of Forming First Impressions

Research has also asked a more general question of how autistic people are perceived by non-autistic others. If autistic people are perceived less favorably, then this could result in avoidance and social exclusion, contributing to the social difficulties they experience. Stagg et al. (2014) found that non-autistic adults rated autistic children as less expressive and less attractive than the non-autistic children based on brief videos of them. Meanwhile, children rated them lower on a variety of evaluative dimensions. In a study using a much larger sample of adult participants, Sasson et al. (2017) carried out three studies in which they showed that non-autistic adults rated autistic adults and children less favorably than non-autistic adults and children on a wide variety of evaluative dimensions, as well as indicating reduced intentions to engage with them.

Further research by Sasson and Morrison (2017) examined the impact of providing diagnostic labelling information on the impressions formed. They compared non-autistic participants' judgments of video participants displayed with either no label, or the correct diagnostic label, or the alternative label (e.g., labelling the autistic person as having no diagnosis). Autistic and non-autistic participants were rated more positively when labelled as autistic than when no label or the alternative label was provided, although this did not completely eradicate the tendency to form more negative impressions of the autistic participants. Moreover, raters with higher levels of autism knowledge gave more favorable ratings to correctly labelled autistic participants. Taken together, these results suggest that diagnostic disclosure might reduce negative first impressions of autistic people, especially for people with greater knowledge about autism.

Studies of Metaperception

Some researchers have combined elements of mindreading and impression formation by examining metaperception, which is the ability

to form an impression of what others think about us. Sasson et al. (2018) investigated metaperception using the same videos from Sasson et al. (2017) and Sasson and Morrison (2017b). Video participants were asked to estimate how they thought others would perceive them on a wide range of personality traits, and then observers judged them on the same traits after viewing their video. They found that autistic participants were less accurate than non-autistic participants in judging how they would be perceived as others, because they overestimated how positively they would be perceived.

While Sasson et al. (2018) study asked participants about how they come across to others in general, Usher et al. (2018) studied impressions formed by dyads of adolescents where one member of the dyad was autistic and one was not, who engaged in a 5-min conversation. Autistic participants were found to be more accurate in judging whether the non-autistic partner liked them than non-autistic participants were. This is consistent with non-autistic people having difficulty interpreting autistic people and suggests that autistic people may be adept in using social feedback from a specific person to gauge how they are perceived by that particular individual.

Metaperception has also been investigated between dyads of autistic and non-autistic people who know each other well. Heasman and Gillespie (2018) used the Interpersonal Perception Methodology (IPM) to investigate perceptions and misperceptions for dyads of autistic individuals and their family members. Both groups predicted that the other would rate them differently than they had themselves on a number of characteristics, evidencing an ability to take a perspective distinct from their own. Moreover, there were few differences for either group between predicted ratings of the other and actual ratings made by the other, such that both groups were fairly accurate in estimating others' perceptions. When asked about reasons for misunderstandings, family members tended to cite an extreme impairment in social understanding of the autistic person, while autistic participants themselves reflected

on both the self and other as causes of misunderstandings.

A further double empathy barrier regarding metaperception may also relate to how autistic and non-autistic people see themselves relative to each other. Research conducted by Gernsbacher et al. (2017) explored the effect of manipulating the context (e.g., with whom) and reference (e.g., according to whom) on questionnaire items of the Broad Autism Phenotype Questionnaire (designed to measure autistic traits). In their first experiment, autistic and non-autistic participants completed the questionnaire where the context specified their outgroup, e.g., for autistic participants an item would read "I like being around non-autistic people." Both groups of participants self-reported more autistic traits when the context group was specified to the participants' out-group. Yet autistic participants reported having fewer autistic traits when the reference-group was specified to their in-group, e.g., for autistic participants an item would read "according to autistic people I have unusual eye contact." These findings highlight that a disjuncture between autistic and non-autistic people exists for both parties in how they view themselves relative to each other, and that autistic people report fewer autistic traits when the reference group was other autistic people.

Heasman and Gillespie (2019b) examined metaperception through a video game where typically developing participants were led to believe they were interacting with another online player to complete a maze when in truth all players interacted with an AI that was programmed to behave the same way. The diagnostic status of the AI was manipulated across three groups of participants to be autistic, dyslexic, or having no diagnostic status at all. The findings highlighted that when the AI was believed to be autistic, they were seen as significantly more intelligent; however, they were also seen as less helpful. Moreover, participants believed they were more helpful when the AI was believed to be autistic, despite there being no behavioral evidence of this. Such disparity between perceptions of being helpful and actual

helping behaviors towards autistic people may further contribute to DEP effects, alongside stereotyped beliefs associated with autistic intelligence and sociability (Heasman 2018).

Overall, studies of metaperception suggest that autistic people are quite good at estimating how specific others perceive them but may have some difficulty judging how they come across in general. Consistent with the DEP, non-autistic people demonstrate difficulty working out how they are perceived by familiar and unfamiliar autistic people.

Neurodiverse Interactions

It has been observed that autistic people appear to have a greater affinity with other autistic people than non-autistic people generally do (Chown 2014). This raises the possibility that autistic people may show improved, if not superior, understanding of other autistic people and may consequently show few signs of “social impairment” in the company of their in-group. Heasman and Gillespie (2019a) examined 30 naturally occurring interactions between autistic adults playing video games, focusing on neurodivergent intersubjectivity, the process through which neurodivergent people develop shared understanding. Their research identified a particular pattern of social coordination that flourished between autistic interlocutors, where the tendency to describe in detail one’s own interest and experiences provided ample opportunity for other autistic interlocutors to discover points of interest and reciprocate with their own stories and ideas. Similarly, the tendency for autistic interlocutors to have a low expectation for tight coordination (an expectation often enforced in neurotypical interactions) resulted in flexibility for autistic participants to explore individual and cooperative ways of making sense of their environment. Specifically, these features of generously sharing one’s ideas and not enforcing an expectation that every exchange should result in reciprocation were complimentary, a pattern which is unlikely to flourish in autistic to non-autistic interaction which take place against the backdrop of normative interaction expectations (Heasman 2018).

Further support for double empathy observed within interactions was highlighted in research by Crompton et al. (2019) who examined information transfer between autistic adults, neurotypical adults, and mixed groups of autistic and neurotypical adults along a diffusion chain (groups of eight participants passing information from one person to the next). Their study observed a significantly steeper decline in the retention of detailed information in chains consisting of autistic and neurotypical participants. Chains only consisting of autistic participants showed similar levels of information retention compared to chains of neurotypical participants, suggesting that it is specifically the interface between autistic and neurotypical communication where problems arise. Furthermore, rapport ratings were lower in mixed chains than autistic- or neurotypical-only chains highlighting that perceptions of sociability are also framed differently depending on the interlocutors.

Morrison et al. (2019) examined unstructured conversations between dyads consisting only of autistic people, only of typically developing people, and mixed dyads of autistic and typically developing people. All participants completed a rating evaluation of their partner after the conversation. Their results showed that on the whole autistic people were rated as more awkward, less attractive, and less socially warm than typically developing people by both typically developing people and autistic partners. This suggests that some aspects of social interaction associated with autism are invariant to the disposition of the perceiver and target. However, their study also found that autistic people had better social affiliation with other autistic people, evidenced by sharing more about themselves and a greater interest in future interactions.

It should be noted that other studies have been less successful in demonstrating an in-group advantage in perception towards autistic people. For example, Brewer et al. (2016) found that both autistic and non-autistic viewers were poorer at identifying the emotions posed by autistic participants, suggesting that emotion expression in autism may be idiosyncratic to the individual. In Edey et al. (2016), no in-group advantage was

observed: autistic viewers were equally able to identify the mental state depicted in animations created by autistic and non-autistic participants. Nevertheless, more research is needed in this area as it remains possible that an in-group advantage in understanding may be more evident natural contexts.

Interventions Addressing the DEP

The DEP has been incorporated into a number of autism training and intervention programs. It is one of five elements of best practice in autism that form the National Autistic Society's (UK) SPELL framework, which incorporates measures to reduce the double empathy gap. Other autism interventions that target the social situation rather than solely the autistic person also have the potential to ameliorate DEP effects. For instance, ATLASS training by Studio3 focuses on acknowledging how the context (carer or service staff) influence the autistic person's behavior, mediated by levels of stress. AT-Autism also include elements of the DEP in their Synergy program which is for professionals working in schools and aims to develop their understanding of how various factors including aspects of the social environment affect the autistic child's experience of the world. Further research is needed to evaluate such interventions taking into account perspectives of both the autistic and non-autistic participants.

Future Directions

Expanding the current evidence base for the double empathy problem will help to improve understanding about the processes through which it occurs, its scale and impact across different contexts of social life, and possible interventions that can ameliorate its negative social effects for both autistic and non-autistic individuals.

Further research could explore the empirical link between being misunderstood or perceived negatively and measures of quality of life (e.g., mental health) (Milton and Sims 2016). A variety of factors could be investigated with respect to

this relationship. For example, the effects of a two-way breakdown in empathy and understanding may result from a difference between monotropic individuals, who have the tendency to localize attentional resources on a specific interest to the exclusion of other potential inputs, and polytropic individuals who are capable of spreading their attentional resources to multiple inputs simultaneously (Murray 1992; Murray et al. 2005). Further research on the link between the DEP and monotropism could shed light on the developmental origins of the DEP, particularly given that most research to date has focused on adults, but we might assume these difficulties arise as a consequence of a transactional, albeit socially situated, developmental process. Another feature to explore is the role of culture in amplifying misunderstandings. Milton (2014b) explored theoretically to what extent the DEP is culturally embedded, given the different representations and approaches to autism in popular culture and suggested that culture may contribute to some difficulties in "interactional expertise" (Collins and Evans 2007) between autistic and non-autistic people. Cultural misinterpretations are an area of interactional difficulty that are easier to change than one's dispositional nature, thus in addition to developing new, holistic interventions, the DEP may also have implications for updating existing interventions, which often place social normativity as an assumed improvement on quality of life, when this is not always the case (Milton 2016b).

The DEP may have important application to a number of different areas of social life, particularly for older autistic populations who experience rapid increases in the size and diversity of their social networks as they progress through adolescence and adulthood (White et al. 2009). For example, as mentioned above, the DEP may help to explain why so many autistic adults have such high comorbidity with mental health issues. Pressures for children to become independent in late adolescence can place an increasing strain on family relationships, which may be amplified by the DEP effects especially if autistic people are disproportionately held accountable for breakdowns in understanding (Heasman and Gillespie

2018). Breakdowns in family relations may consequently deny autistic people of the few social supports available and could detrimentally impact perceptions of autism acceptance (Cage et al. 2018). Future directions for research should examine the perspectives of autistic family members in addition to autistic people themselves to identify the supports required as they transition towards being an informal carer.

Finding and retaining employment for autistic people is another context in which the DEP is particularly salient. The social encounter of the job interview and the difficulty in managing professional relations (which are qualitatively different from all other relationships) are two environments governed by complex roles, norms, and expectations which can easily lead to misunderstandings (Hendricks 2010). Future research can examine employers' potential biases in social perception of autistic adults which may impede progress in job interviews and daily working tasks. This may help to identify the contributing factors towards the current autism employment gap observed in many countries.

The DEP may also help to shed light on the numerous encounters autistic people face as they progress through the justice system, such as providing a police statement or testimony in court. In such interactions, autistic people will be highly anxious potentially reducing their credibility as their behavior and intentions are susceptible to misinterpretation. In addition, research has shown that autistic people have difficulty in recalling events personally experienced (Maras and Bowler 2014), thus future directions for research can examine the perspectives of magistrates in interpreting and scaffolding such recall, as well as the impressions that jury members may take from such encounters.

Late diagnosis of autism can leave many autistic adolescents and adults facing a variety of neurotypical interactions as they attempt to access support and services for their disability. The process of assessing disability needs may be further complicated by masking and camouflaging (Dean et al. 2017) and anxiety about outcomes both in terms of financial support and impacts on one's identity (Kite et al. 2013). Moreover,

research on other disability assessment procedures have highlighted the difficulty in translating one's impairment into criteria on assessment forms since caregivers and care-receivers have divergent perspectives on the burden of care (Moore and Gillespie 2014). Further research should therefore examine the DEP in terms of the perspectives involved in the social encounters experienced throughout the diagnostic pathway, and the institutional barriers that exist between the disabilities experienced and the instruments used to measure the support needs of disabilities.

Sexuality, sexual health, and gendered self are important frontiers for future research on the DEP since one's sense of self is relationally formed (Dewinter et al. 2017; Yergeau 2017). In addition to misunderstanding autistic perspectives, the complex sensory needs many autistic people experience may further contribute to misalignment of perspective in sexual encounters. Autistic vulnerability in social understanding means there is great risk of potential harm or abuse that might result from DEP misunderstandings in intimate relationships. Further research should explore these risk factors to inform education and support provided.

Finally, the DEP also has epistemological implications in terms of participatory and emancipatory research. The two-way nature of misunderstandings that are observed in interpersonal relations also exist between researcher and participant. For example, in the UK, autistic adults report a mismatch between their priorities for research and the funding for autism research, which should focus more on how to make a difference to people's day-to-day lives (Pellicano et al. 2014). It is therefore important that research design and engagement benefit from autistic involvement (Milton and Bracher 2013; Milton 2014b) in order to have a positive impact on outcomes for autistic people (Fletcher-Watson et al. 2019).

Double-Blind Study

Lawrence David Scahill

Nursing and Child Psychiatry, Yale Child Study Center, Yale University School of Nursing, New Haven, CT, USA

Marcus Autism Center, Children’s Healthcare of Atlanta, Atlanta, GA, USA

Department of Pediatrics, Emory University, Atlanta, GA, USA

Definition

DOUBLE-BLIND TRIAL. The double-blind trial is a research method that attempts to reduce the

bias in research studies. In the classic double-blind trial, subjects are randomly assigned to receive an active medication or a placebo. The placebo is formulated to look and perhaps even taste like the active medication – but the placebo contains no active ingredients. We use the term “double-blind” to indicate that investigators and patients (and parents) do not know whether the patient is getting the active medication or the placebo. The treatment mask is intended to reduce bias and expectation.

When a new medication is being introduced, there may be a lot of interest and hope for the new medication. In the absence of placebo control, this interest and hope could lead to false impressions about the benefits of the medication. Indeed, high expectations can also contribute to the so-called “placebo effect.” In several recent studies in children with autism spectrum disorders, as many as one third of the subjects on placebo were classified as much improved or very much improved. For example, in the citalopram study (► [Citalopram](#)), 34% of the subjects randomly assigned to placebo showed a positive response rated by clinician who was blind to treatment assignment.

Several elements are essential in the conduct of a double-blind, placebo-controlled trial. First and perhaps most important is random assignment. Random assignment is essential to ensure that the two treatment groups are similar. Second, there should be a match between the entry criteria and the study treatment. For example, in the risperidone trial conducted by the RUPP Autism Network (► [Citalopram](#)), subjects were required to have serious behavioral problems. This ensures that there is room for improvement on the target clinical symptoms. This is important for ethical and statistical reasons. It is fair to compare a new medication to placebo when it is unknown whether the new treatment is effective. In most situations, however, it seems unfair to enroll subjects into a medication study if it was known that the active treatment has a low chance of conferring benefit. In statistics, investigators are interested in finding out if the new treatment is superior to placebo. Subjects who have low severity on the clinical target have little room for improvement, which will make it difficult to detect change.

Finally, there is the issue of sample size. A trial that is too small cannot answer the question whether the new medication is superior to placebo. This could be unfortunate if a beneficial treatment is abandoned too soon because it failed to show efficacy in a small trial. On the other hand, treatment trials are expensive.

Moreover, we are asking subjects and families to consider randomization to placebo. A trial should only be as large as needed to test whether the new treatment is superior to placebo. Investigators have to determine the minimum magnitude of benefit that would be considered clinically meaningful and then calculate the sample size needed. The “minimum clinically meaningful benefit” depends on the treatment target. For example, self-injurious behavior is a serious problem. Even a modest level of benefit might be considered meaningful. Repetitive behavior such as rocking or watching the same video over and over can be problematic – but not as severe as self-injury. For a less severe behavior, a higher level of benefit might be demanded of a new treatment. In general, the smaller the difference between medication and placebo, the larger the trial has to be.

Douglass Developmental Disabilities Center

Lara Delmolino and Sandra Harris
Douglass Developmental Disabilities Center,
Rutgers, The State University of New Jersey, New
Brunswick, NJ, USA

Major Areas or Mission Statement

The Douglass Developmental Disabilities Center (DDDC) is a unit of the Graduate School of

Applied and Professional Psychology at Rutgers, the State University of New Jersey, and is located in New Brunswick, New Jersey, on the Rutgers campus. The DDDC opened in 1972 to serve children with autism. Because of the university affiliation, the Rutgers Board of Governors had to officially approve its establishment. In the beginning, there were nine children, two teachers, and several graduate students as well as a small cohort of undergraduates from the university.

Landmark Contributions

In the decades since its modest start, the DDDC has steadily expanded its services and refined its mission. The current tripart functions of the DDDC are to (1) serve people on the autism spectrum and their families, (2) educate undergraduate and doctoral students in the latest methods of treating people with autism spectrum disorders (ASD), and (3) do research on questions of importance in the treatment of people with autism and on meeting the needs of their families. From its inception, the DDDC has relied on the principles of applied behavior analysis (ABA) to guide services. As the teaching strategies derived from ABA have grown more elegant and precise, so too have the teaching methods at the Center. Methods that were once at the heart of practice in the 1970s have evolved steady into the more effective and extensively studied techniques in use in the twenty-first century.

Major Activities

Direct Service to People with Autism

Two units at the DDDC are devoted to center-based direct instruction of people with autism. These are the Douglass School and Adult Services.

The Douglass School is approved by the New Jersey Department of Education as a “college-operated program” to serve children and adolescents from 3 to 21 years of age with autism spectrum disorders (ASD) who need a specialized setting to address their educational needs and behavior intervention services to address

inappropriate behaviors. Because of a very intense staff to student ratio, the Douglass School has sufficient staff members to address the unique needs of each learner. Both skill acquisition and behavior reduction programs for all learners regardless of age are based on the science of applied behavior analysis. Specific strategies vary based on the needs of the learner and the most current empirically validated and least intrusive strategies that meet the needs of each individual. Families are urged to be active in the education of their children and are provided with training in ABA teaching methods as well as being invited to do regular observations at the Center. In addition to work in the classroom and at home, every effort is made to bring students into the community so they can use their skills in the settings where they will be most appropriate.

The DDDC’s Small Wonders Preschool is an integrated classroom that has both children on the autism spectrum and typically developing peers who serve as role models for age appropriate behavior. This classroom model, which was opened in the early 1980s, has been adopted by other programs in the public and private sector. Over the years, approximately half of the target children served in this classroom have left the Center for a regular education classroom in a public or private school.

The adult services program serves adults with autistic disorder and intellectual disability who are 21 years of age or older. These adults either continue to need a very intense adult to client ratio and/or have other significant challenges that make it difficult for them to be in a less specialized adult program. The Center’s objective for every person in the adult program is to integrate them as fully as possible into the community. As of 2011, a little under a quarter of the adults spend 5 days a week in community vocational settings, the majority of the other adults spend 3–4 days a week in a community vocational setting, and it is a rare for an adult client to have no vocational activities outside of the Center. These vocational placements include janitorial work at local restaurants, yard work both on and off of campus, house cleaning, and doing basic clerical work in offices including filing, copying, and other support tasks. In addition, among those adults who are not

engaged in vocational tasks 5 days a week, all of them take part in community-based recreational activities. The parent of one adult at the center created a private entity called “Men with Mops” that bills private individuals and companies for the services the adults provide and issues paychecks to the workers.

Consultation to Schools and Families

In addition to direct service to people with autism, the Center also provides extensive consultation services to public and private schools in the New Jersey, New York, and Pennsylvania area. These services are provided by staff members working for the DDDC’s Outreach Services. Schools sign contracts with Outreach Services to provide in-class consultation to teachers who have children with ASD in their classrooms or for support in establishing an in-district applied behavior analysis program. These consultations vary from once or twice a month to several days a week depending on the needs and request of the school district. Some districts contract for a brief period and others draw on these consultation services for many years to ensure that their teachers continue using state-of-the-art ABA techniques as those methods evolve.

Outreach Services also provide two kinds of home-based services. One of these is early intervention for children under the age of 3 years and the other is home-based services on a full-day basis or after the child’s school day has ended.

The early intervention program (EI) serves infants and toddlers younger than 3 years of age in their own homes. In addition to direct services to the child by the home consultant, parents are also taught the ABA intervention techniques so they can use them in their daily interactions with their child. Among the older children who receive home-based services about 30% have full day/4 or 5 days a week intervention. The rest of the families receive services after school or on a part-time basis during the day. Again, these services are based on the principles of ABA and typically involve direct instruction to the child as well as helping parents master the techniques so they can apply the ABA methods on their own.

Other Services to Families

In addition to educational/treatment services through Douglass Outreach, the DDDC provides assessment and diagnostic services for families and schools. This includes diagnostic assessments, intelligence testing, speech and language assessments, and learning evaluations. The Center has a group of full-time staff and part-time consultants who do these evaluations and make treatment recommendations. Douglass Outreach Services have an NJ Department of Education–approved child study team for providing second opinions at the request of families and/or schools. Outreach Services staff members also do functional assessments of problematic behaviors for schools and families and make detailed treatment recommendations based on these assessments.

Educating Undergraduate and Graduate Students

Educating undergraduate students about autism and behavioral intervention strategies has been at the core of the DDDC’s mission since its inception. Junior and senior undergraduate students at Rutgers University can enroll in fieldwork in psychology. Through the field work course, 40–50 undergraduates per semester participate in one day per week of clinical work in a classroom for students or adults with autism. Their hands-on clinical training is supplemented by didactic training and lectures by the DDDC’s teachers, graduate teaching assistants, and faculty. Fieldwork training covers topics such as behavioral intervention, applied behavior analysis teaching strategies, assessment, curriculum, and characteristics of autism. Undergraduates are able to take a second semester of fieldwork and participate in an advanced seminar while continuing their clinical experience.

Undergraduates are also able to enroll in a research methods class focusing on single-case design and applied behavior analysis research methodology. A small number of students enrolled in the research course each semester spend 10 h per week participating in ongoing DDDC research projects and activities such as running experimental sessions, integrity and reliability data collection, literature review and

critique, and data coding and compilation. Students are also active in a weekly seminar led by a senior graduate student.

Graduate training at the DDDC takes place in one of three ways. Primary graduate training experiences are available to the full-time doctoral program in clinical psychology through the Graduate School in New Brunswick and the Graduate School of Applied and Professional Psychology at Rutgers, the State University of New Jersey. Graduate students are offered practicum positions or graduate assistantships at the DDDC. Graduate students serve as behavioral consultation staff and support in the assessment and treatment of challenging behavior, while also supporting case management and behavior analytic research. Advanced doctoral students also support the DDDC's research mission while conducting independent theses and dissertations. Graduate students gain experience in teaching by coordinating the undergraduate courses in fieldwork and research.

Other graduate training at the DDDC takes place through the University's Center for Applied Psychology and Continuing Education program. Graduate students from other university departments and professionals from the general community can enroll in a series of graduate courses taught by DDDC faculty. These courses are designed to fulfill the academic requirements for becoming board-certified behavior analysts.

The Research Mission of the DDDC

The research mission of the DDDC is to explore best practice behavior analytic treatments for autism and contribute to the dissemination of research to support their use. Research activity at the DDDC is driven by the clinical needs of clients at the Center and the needs of the general and scientific communities to which we belong. As such, the focus of the DDDC's clinical research shifts according to the presenting needs of the students and the status of the science in the field of behavioral autism treatment.

The DDDC also works collaboratively with researchers across different disciplines at the University and at other University settings, by supporting recruitment, methodology consultation,

and providing autism expertise to projects by multidisciplinary research teams.

Current and ongoing research themes in the DDDC research plan are the evaluation of behavior analytic teaching strategies, methods for assessing and intervening with challenging behavior, impact of autism on families, and methods for assessing and predicting treatment outcome and progress in behavioral treatment.

Down Syndrome

Fred R. Volkmar

Child Study Center, Irving B. Harris Professor of Child Psychiatry, Pediatrics and Psychology, Yale Child Study Center, School of Medicine, Yale University, New Haven, CT, USA

Synonyms

[Down's syndrome](#); [Trisomy 21](#)

Definition

This condition, first described by Langdon Down in the 1860s, is caused by the presence of three copies of chromosome 21 (trisomy 21). The trisomy can reflect an entire extra copy of chromosome 21 or a partial one (the latter due to translocation). At one time, a very common genetically caused form of intellectual disability, the frequency has decreased given the potential for diagnosis early in the pregnancy. Both cognitive difficulties and characteristic features and medical problems are present.

Overall, cognitive level is typically in the mild to moderate range of impairment (average IQ 50).

Individuals with mosaic Down syndrome (where only some cell lines exhibit the trisomy 21) may have higher IQs. Physical problems include slow physical growth and characteristic features such as unusual facial appearance (due to a round face, epicanthal folds, small chin, and large tongue). Cardiac defects are frequent. Other medical problems can include seizures, ear infections, thyroid problems, as well as leukemia and higher rates of Alzheimer's disorder. Educational interventions focus on fostering overall development and adaptive skills to achieve the highest possible functional outcomes in adults.

Interest in Down syndrome relative to autism arises for several reasons. It has frequently been the case that individuals with Down syndrome have been used as control or comparison groups in studies of autism. There has also been an impression that Down syndrome individuals are typically more social than might otherwise be expected given their cognitive level although several case reports suggest that Down syndrome and autism co-occur. Howlin et al. (1995) described four such cases and emphasized the importance of correct diagnosis of both conditions to be able to provide appropriate services.

Drama and Autism

Carmel O'Sullivan
 Trinity College, University of Dublin, Dublin,
 Ireland

Definition

I regard the theatre as the greatest of all art forms, the most immediate way in which a human being can share with another the sense of what it is to be a human being.

Oscar Wilde (as cited in Corbett et al. 2011)

Drama interventions attempt to provide creative, enjoyable, and engaging opportunities for people with autism spectrum disorders (ASD) to practice a wide range of social skills in the safety and protection of a workshop environment. Ranging from whole group to one-to-one settings, drama interventions operate on the basis of the creation of a fictional context (i.e., a pretend situation), which playfully captures the attention of the participants and encourages interaction and communication with others. Operating on a continuum, there are several different approaches to using

drama as an intervention with people with ASD, varying from involvement in theater performance and working on play scripts at one end to improvisation and simulation at the other. Underpinning all forms of drama interventions is an intention to actively involve the participant in exploring and making sense of the world in which they live and working creatively with them to understand their place and their relationship with others in that environment. Drama interventions are structured, arts-based, educational mediations, involving a facilitator, teacher, or therapist who draws from a range of creative and fun teaching and learning strategies to actively involve the participant in learning for increased social awareness, communication, and understanding. Typically, both participants and facilitators take on roles ranging from simple two-dimensional roles, such as pretending to be a shopkeeper, dentist, or grandmother, to highly developed roles such as pretending to be a superhero going on a mission to defeat Lord Taylor and save the world.

“Going into role” is an important defining characteristic of drama interventions and often involves a facilitator “in role,” improvising an everyday situation with the participants who may take on a different role and respond/react to the situation as it unfolds in a workshop setting (commonly referred to as role-playing; see O’Sullivan 2011). These roles can be swapped and developed, adding in new complications or changes each time a scene is replayed. Alternatively, if participants are socially and cognitively able for it and in particular if they are able to differentiate between fiction and reality, both facilitator and participants can “go into role” and engage in exciting, action-filled, improvised drama, which facilitates the practice and exploration of a wide range of personal and social skills. During such interventions, both participants and facilitator together try to unravel and solve various fictional mysteries and problems (this activity is typically referred to as drama in education or process drama; see Howell and Heap 2013; Edmiston 2014). The former approach is often used in drama therapy settings on a one-to-one basis or with small groups with explicit therapeutic objectives in a clinical setting, and the latter is

most often associated with inclusive classroom practice in schools or in extracurricular drama classes with specialist drama teachers working with groups of between 8 and 14 participants.

Theater as an intervention is typically associated with working from existing scripts or scripts which the group devise/create from their own experiences/interests and which participants rehearse and then perform in front of an audience. In contrast, drama in education places much less emphasis on the performance aspect and highlights the process and value of engaging with fictional scenarios, where there is no script but participants react to the fictional situation in an improvised manner. Drama in education is also commonly referred to as “process drama.” Drama therapy (written as dramatherapy in the UK and several other European countries) is closely related to process drama but is defined as the use of drama as a therapeutic method. Similarly, psychodrama is active and experiential and encourages the spontaneity and creativity of clients for therapeutic purposes.

Historical Background

The use of drama as a social and educational intervention began in the nineteenth century, but drama has been valued for thousands of years for its ability to entertain, educate, and heal (Brockett and Hildy 2007). References to the cathartic and therapeutic effects of both observing and participating in drama and theater performances are replete in the literature, from Sophocles’ *Antigone* in the fifth century BC to the dramatic works of Shakespeare, Middleton, Fletcher, and Ford in the seventeenth century and numerous references to the value of building theaters in psychiatric hospitals in countries such as Italy, France, Germany, and the USA in the eighteenth and nineteenth centuries (Casson 2007). Similarly, the use of drama in young people’s education has long been documented, stretching back to Athenian education and reappearing again in the Renaissance period, when “By the late sixteenth century, almost all schools used drama” (Courtney 1968, p. 19). Harriet Finlay-Johnson (1912/2008) and

Henry Caldwell Cook (1917) began using dramatic play in schools as a specific teaching and learning method in England at the turn of the twentieth century, with evidence of similar practices in use in schools in Croatia, Romania, Poland, and eastern Europe from the mid-1800s. The development of drama in education by pioneers such as Winifred Ward, Peter Slade, Viola Spolin, Brian Way, Nellie McCaslin, Dorothy Heathcote, Gavin Bolton, Betty Jane Wagner, Cecily O'Neill, David Davis, and Jonothan Neelands, throughout the twentieth century, firmly established the role of drama as an effective and creative approach to teaching and learning in formal and nonformal educational contexts. Recognizing that creativity and spontaneity are the propelling forces in human progress, Jacob Levy Moreno was similarly exploring the use of drama with children in Vienna [1908], before later developing its application in therapeutic procedures known as psychodrama and sociodrama (Moreno 1939). Peter Slade (1954), a pioneer in the field of theater for children and whose child drama philosophy was influential in the development of drama therapy, was also an expert in using drama as an intervention with children with special needs, which Winifred Ward had earlier started to develop in the USA in the 1920s.

From the 1960s onward, a parallel approach was developed to working with children and people with special educational needs (SEN). Some practitioners started to specialize in the emerging field of drama therapy, notably led by Sue Jennings (1982, 1987), and others began to work in this area using drama interventions developed by Dorothy Heathcote (Johnson and O'Neill 1984). Both traditions use similar techniques (dramatic play, improvisation, role-play, movement, mime, drama games, use of masks and puppets, and working with scripts, myths, and stories), often with similar equipment, such as dress-up materials, a box of clothes, art supplies, stories, books, and musical instruments. Both share interweaving influences from the areas of drama, theater, and psychology and aim to work on similar skills: expressing and exploring feelings, developing spontaneity, imagination and creativity, improving self-image and self-

confidence, and developing social relationships. However, they have very distinct purposes. Drama therapists use elements of the performing arts in their work and apply it in a clinical setting. It has been defined by Sue Jennings (1982) as "the specific application of theatre structures and drama processes with a declared intention that it is therapy," while Moreno (1983) described its forerunner psychodrama as "the science which explores the truth by dramatic methods. It deals with inter-personal relations and private worlds." An explicit emphasis on using drama as a therapeutic method in a clinical setting differentiates these practices from other forms of drama interventions, which focus on more general development and practice of personal and social skills and thus feature more prominently in the literature about interventions for people with ASD.

Despite the fact that Viktorine Zak, a nurse at the Vienna Children's Hospital where Hans Asperger worked, developed drama programs to teach social skills to children with ASD in the 1940s (Asperger, [1944], as cited in Attwood 2007), there has been little sustained attention to its use in the intervening period and even fewer published studies discussing the use of drama and theater interventions with people with ASD. Passing mention of drama is made when discussing functional or symbolic play as a social skills intervention. References to structured social and sociodramatic play (Conn 2007) and role-play (Nelson 2010) predominate in the field (the former particularly in early years settings), with limited reference to participants engaging in theater performance (Schneider 2007; Vickers 2005) or drama interventions (Sherratt and Peter 2002; O'Sullivan et al. 2009; 2010). However, despite its poor presence in the scholarly literature, online information is available about several recently established programs, associations, and professional publications and magazines dedicated to the use of theater and drama interventions with children and young people with ASD. Notable examples include Andrew Nelson and Parasuram Ramamoorthi's "Applied Theater Research and Autism Network" (ArTRAN) and its associated "Velvi Theater Heals" organization based in India; Stanley Greenspan's "Floortime," which inspired

Elaine Hall to establish the well-known “Miracle Project” in California leading to the release of “Autism: The Musical”; the Autism Theater Network (part of the Applied Theater Center); “Social Drama” being developed by Carmel O’Sullivan in association with ASPIRE (the Asperger Syndrome Association Of Ireland) in Dublin, Ireland; Theater Horizon; Face Place Theater Project in Indiana; Social Emotional NeuroScience Endocrinology (SENSE) Theater in California; People’s Light & Theater in Pennsylvania; and ArtStream in Washington, D.C. in addition, and several professional theater companies and playhouses have established programs involving what they describe as the use of occupational therapy and therapeutic interactive performances for and with young people with ASD, such as at the Florida Repertory Theater Company, Des Moines Playhouse in Iowa, and the Red Kite Project at Chicago Children’s Theater. The first autism-friendly performance on Broadway took place in 2011 (*The Lion King*) and has become one of the fastest growing services for people with communication barriers (Mandell 2013).

Rationale or Underlying Theory

ASD is characterized by differences in social communication and restricted interests and repetitive behaviors. Although individuals with a diagnosis of ASD have uneven cognitive and social skills profiles, they are all likely to experience a degree of challenge in the areas of pragmatics (the social use of language) and social cognition (being able to see things from another person’s perspective). It is acknowledged that teaching such skills should best be attempted using concrete materials and opportunities to make abstract concepts meaningful and tangible. However, they are often taught in isolation of real world, authentic contexts, which limits generalizability to other situations beyond the confines of the treatment room or classroom (O’Sullivan et al. 2010). In contrast, all drama interventions, whether theater, therapy, or process drama oriented, place participants in fictional roles and situations, many of which mirror or represent real life and which

require social communication, problem-solving, working in pairs/small groups and in whole group activities, being flexible and receptive to other’s ideas, constructively building on their suggestions, negotiating, collaborating, cooperating, and exercising global and social observation skills rather than local and physical processing (Russell-Smith et al. 2012; O’Sullivan et al. 2012). Drama interventions engage participants experientially, introducing them to fictional situations and stories, and somewhat larger than life, colorful characters who attract their curiosity and attention on a number of levels: emotionally, cognitively, personally, and socially. The intention is to engage participants in an exploration of that character’s life and to actively participate in following that journey, working collaboratively with peers and supporting teachers/facilitators to resolve various exciting and challenging situations as they arise (O’Sullivan et al. 2010).

As emotional education of people with ASD is an important component of their development (Sappok et al. 2014), drama interventions operate on the premise that emotions are rational and cognitive in kind and therefore can be educated (Best 1992). In drama interventions, the techniques used typically focus on communication skills and building social relationships rather than emphasizing only the dramatic or theatrical art form, as would be the case in professional actor training. Drama interventions are the medium through which people with ASD can encounter a range of human experiences and are offered the possibility of considering ideas from different angles and perspectives while expanding their conceptual horizons, deepening their understanding of human behavior, and, in so doing, appropriately educating their emotions and increasing their empathy with others.

Drama interventions draw from the traditions of dramatic play, process drama, theater, and developmental psychology, particularly:

- The “as-if” mode of thinking necessary for spontaneous make-believe play (Taylor and Warner 2006)
- Theater (Brook’s *Empty Space*, 1968, and Boal’s spect-actor, 2002)

- Education (Dewey's progressivism, 1938, and Vygotsky's social constructivism, 1978)
- Anthropology (ritual and myth, Schrader 2012)
- Social, developmental, and clinical psychology (object relations, symbolic interaction theories, and personal construct psychology, Langley 2006)

Drama theorists have developed strategies to create a safe and structured environment for participants. These include such techniques as a "drama contract" to diminish potential behavior management issues and distancing conventions so that participants are removed in time and space from the characters they are exploring or the roles they are playing (Jones 2007; Chasen 2011). This facilitates an important objective distancing from the participants' own lives, but experiences are gently resonated back to the individual through periods of planned reflection in each session. Techniques such as "protection into role" and "protection into emotion" (Davis 2014; O'Sullivan 2011) gently ease participants into role without placing social and communication demands on them for which they may not yet be ready.

It is in the domain of what are traditionally called "soft skills" that the use of drama interventions can play a role, pushing the boundaries further than what can be achieved through social skills interventions alone. Drama's relevance as an intervention with people with ASD is through its ability to create stories in which participants come face to face with the world: recognizing their world and their relationship to it (Davis 2014). Heathcote (Johnson and O'Neill 1984) developed a series of drama conventions, which allow participants to engage with the world from different perspectives, to see things from different points of view. This approach fits well with the theory of mind. Taking on a role in drama in education allows the participant to "stand in the shoes" of another person and respond to the unfolding fictional story "as if" they were that person. The key difference between this approach to drama and more formal theater approaches is that in the latter, the participant

often takes on the full set of attributes of a *character* (rather than a role), imitating how they walk, talk, and behave, which many people with ASD are good at and enjoy doing but which reduces the educational potential of the intervention, as the participant metaphorically "steps out of *character*" as soon as the activity is over and leaves much of the learning entailed in the experience behind in the rehearsal room or workshop. In drama education and drama therapy approaches, the participant takes on only a few of the characteristics of the role they are playing, and thus they are able to self-spectate, i.e., observe themselves playing that role and learn from the experience through reflection both during the drama and afterward (O'Sullivan 2011). It increases the potential for transferability of social communication skills, imagination, and flexibility into other settings beyond the immediate drama context.

Goals and Objectives

Drama interventions are closely related to social, symbolic, cooperative, and pretend play, social interventions, and social skills interventions. However, in drama the work is generally developed more in the domain of exploration, experiential learning, and reflection rather than focusing on the teaching and practice of social communication skills out of context. Drama interventions are intended to facilitate the exploration of pragmatics, social cognition, social imagination, social interaction, social emotional reciprocity, and personal development in contextualized and enjoyable "as-if" situations. Participants are gently eased into a make-believe scenario through the use of character and role and occasionally using props and costume, where they are placed into positions which require them to behave "as if" they are someone else encountering that particular situation and interacting with others, drawing on their personal and social skills repertoire to address and/or resolve the fictional scenario. The overriding objective of using drama interventions with people with ASD is to assist in the development of theory of mind, perspective taking, and

executive functioning [encoding, processing, and integrating social information] (Minne and Semrud-Clikeman 2012; Guli et al. 2013) while simultaneously using pragmatic language skills in a holistic experience where social skills are integrated in real-time experiences rather than being taught in isolation. Drama interventions contextualize social skills in incremental episodes according to the cognitive and social functioning abilities of participants and facilitate exploration and examination of identity (Hodermarska 2013; Goodley and Runswick-Cole 2011), autonomy (Carter et al. 2013), independence, empathy, emotional development, and developmentally appropriate relationships (see Goldstein and Naglieri 2013).

Treatment Participants

Drama interventions are used with children (typically aged 6 and older), with adolescents, and to a much lesser degree with adults, with a wide range of abilities and symptom severity across the autism spectrum. The most common participants are school-age children in extracurricular settings such as social skills and theater groups, although there is some evidence that process drama interventions are being increasingly used in mainstream inclusive educational settings and special schools (Schneider 2007; Sherratt and Peter 2002). Research has indicated that drama interventions are likely to be more successful for children with higher social interaction and communication skills which are often prerequisites for engagement in drama interventions (Chang et al. 2014).

Treatment Procedures

Individuals involved in drama interventions typically participate in one of three broad areas of treatment:

1. Theater and performance
2. Drama in education and process drama
3. Drama therapy and psychodrama

The first two categories do not require referral, and participants (often with support from parents, teachers, or other caregivers and professionals) self-select to attend such activities. In the case of attendance at drama therapy and psychodrama, referral is made to a specialist therapist who assesses the individual's needs and establishes treatment goals and objectives as part of an overall treatment plan, often working within a multidisciplinary team (Silverman 2006). Owing to its explicit therapeutic objectives, drama therapy and psychodrama adhere to strict regulatory guidelines relating to optimum group size, ranging from individual sessions to small group (3–5 people) and large group sessions (more than 6 people), and comply with formal requirements for evaluation and reporting mechanisms (Bailey 2010). Depending on the needs of individuals, the duration of drama therapy may range from 30 to 50 min sessions, one to three times weekly over a period of 10–16 weeks, although longer term therapy can be extended over a period of 2 or 3 years (Chasen 2011).

Participation in drama and theater in education activities typically involves groups of 8 or more subjects, in weekly sessions of 1–3 h duration, over a period of 6 months to a year. Where individuals enjoy participation in these drama interventions, their attendance may continue for a much longer period of time (O'Sullivan 2014). Formal and systematic assessment and evaluation methodologies are rarely used in such practices, where the emphasis is on participating in a highly charged social situation which requires participants to interact in a meaningful way and build social relationships with others in the group (Nelson 2010).

In all three treatment categories, social learning and experience is facilitated through active engagement with the art form of drama and theater which is used as a vehicle to explore:

- Psychosocial difficulties (including cognitive learning difficulties; difficulties related to defining and expressing feelings, interacting with others, planning and decision-making, and understanding the intentions of others;

emotional and behavioral problems; and socially inappropriate behavior)

- Neurodevelopmental difficulties (including difficulties in concentrating, motor coordination, dyspraxia, hyperactivity)
- Mental health/psychological difficulties (including agitation, anxiety, mood swings, loneliness, depression, phobias)
- Behavioral difficulties (including aggressive physical and verbal behavior, conduct disorders, oppositional defiant behavior) (Andersen-Warren 2013)

Each drama intervention session typically involves an opening and a closing activity to mark the beginning and end of the class, where participants are seated in a circle and greet one another, share any stories or “news” they have, and play some warm-up games and drama exercises to nurture the group identity. Opportunities for reflection are usually built in to the structure of each session to allow participants to relate what they have experienced in the drama or theater workshop to their own lives.

Efficacy Information

Despite the fact that social communication skills are core challenges associated with ASD, there is still relatively little attention paid to interventions in this area in the literature, and areas such as sociodramatic play, imaginative play, symbolic play, creative dramatics, arts therapy, play therapy, psychodrama, role-playing, and psychotherapy social skills training are significantly underrepresented in peer-reviewed publications. Not unexpectedly, drama interventions fare even worse and rarely feature in the scholarly literature. This may be related to challenges associated with accurately defining and delineating the scope of practice in this field but also possibly to the nature of engagement with the art form, which until relatively recently did not have a strong tradition in empirical research (Donovan 2011). However, drama interventions have recently begun to appear in the professional literature related to ASD (i.e., online websites, blogs, teaching

manuals, magazines, and videos), which are designed to impact upon and disseminate practice.

Notwithstanding criticisms about research in the area of social skills interventions, which has been beset by a lack of randomized control tests and claims that many studies lack rigorous research designs to assess the effectiveness of interventions, generalization effects, and maintenance (Kaat and Lecavalier 2014), there has been a dearth of systematic research on drama interventions. Apart from a few small-scale case studies involving single subject or small-N design (Kempe and Tissot 2012; Corbett et al. 2011; Wilmer-Barbrook 2013; Pimpas 2013; Dunne 2009), the literature has been largely silent in this regard. This despite increased interest in drama-based treatment programs to ameliorate the symptoms of ASD in recent years and with them, the demand to use evidence-based interventions (EBI) (Livanis et al. 2013).

However, what has emerged positively from those studies undertaken in recent years is the degree of enjoyment, empowerment, and independence, which participants and their parents/carers have reported as a result of being part of social skills and drama interventions (Mandelberg et al. 2014; Loyd 2013a; Guli et al. 2013; Ramamoorthi and Nelson 2011). Notwithstanding the challenges associated with accurately validating changes and progress and indeed accessing experiences of this nature (Shaughnessy 2013), participants themselves have self-reported such changes and developments in their engagement with peers, their self-confidence, and self-esteem, reduction in anxiety, etc. (Trimingham 2013). Participant voice is not a new area in the field of inclusive education (Oliver 1992), and first-person perspectives of people with ASD are beginning to bring fresh insights to this area of research (Kirby et al. 2014). For example, Loyd’s (2013b) study of 10 young people with autism in a drama education intervention program argues for the active involvement of people with autism in research about them.

In a study involving a drama in education intervention with two girls with ASD in a special school setting with other students with moderate intellectual disabilities, Kempe and Tissot (2012)

reported positive gains in participation in group work, language use, development of imagination and humor, and sustained engagement with a fictional character which led the participants into the practice of social skills that had relevance beyond the confines of the classroom. Trowsdale and Hayhow (2013) report similar progress in their case study of one boy with ASD (in a larger sample of participants with learning disabilities) who demonstrated marked improvements in identifying and regulating his emotions, developing a playful relationship with another child, and enhancing his imaginative and creative abilities. Using mimetics and theater methodology, they record reductions in ritualized activities and positive developments of the case study on the child's personal and social identity. Employing a similar methodology, researchers from Butler University (Loer 2012) engaged in a 10-week collaborative study with the Pathway School and People's Light & Theater Company, involving eight adolescents in rehearsals of Mark Twain's *The Adventures of Tom Sawyer*, in which repetition and learning lines, mimicry, and exploration of emotions were key elements. Further eight students from the same school served as a control group. Participating students exhibited significant improvement in four behaviors: displaying appropriate emotions, offering help without prompting, controlling temper, and acknowledging the perspective of others.

Corbett et al. (2011) identify close links between theater and modeling techniques, and in a 3-month pilot project involving the pairing of peer actors with participants with ASD, researchers noted some promising potential for social skills training in a nurturing and fun environment. Using a unique performance-based social skills curriculum called SDARI (Sociodramatic Affective-Relational Intervention) and employing affectively engaging improvisation games and dramatic training adapted for people with ASD, Lerner et al. (2011) suggest that increased social assertion, improved ability to detect emotions in adult voices, and decreased social problems may be encouraged by participating in this drama-based intervention. In a recent meta-analysis of social skills interventions, Kaat and Lecavalier (2014) refer to the potential of

further investigating performance-based (specifically drama-based) interventions, such as those described above by Corbett et al. (2011) and Lerner's SDARI (Lerner and Mikami 2012; Lerner et al. 2011).

In a counterpoint approach to mimesis, Shaughnessy (2013) describes a research project with 22 children called "Imagining Autism" which explored the potential of drama as an intervention to challenge the stereotypes surrounding ASD. The approach adopts a nonmimetic scenography requiring new modes of theatrical perception and demanding an active form of participatory spectatorship. In "Imagining Autism" (www.imaginingautism.org), participants recognized that they were performers and authors and at liberty to improvise and play within a process-based contemporary performance.

The studies cited above all relate to a work carried out with children and adolescents, but similar gains have been reported in projects with adults. In a study of 18 adults with ASD, participants referred to their attraction to theater-based interventions, such as improvisational theater classes, the writing of dramatic scripts, participation in role-playing games and voice workshops, which most respondents described as allowing them an opportunity to practice social skills and reduce social anxiety. In the words of one respondent, "by doing [improvisational theater], you realize that it's actually possible to be spontaneous, to just go with an impulse (laugh)" (Müller et al. 2008).

Preliminary evidence exists to support some degree of generalization of skills to settings outside of the drama intervention group, but a major limitation of the studies conducted is the small number of participants, which limits the generalizability of results.

Outcome Measurement

Increasingly, drama therapists and drama facilitators are being asked to demonstrate the effectiveness of their work through evidence-based practice (EBP) and practiced-based evidence (PBE) (Dokter and Winn 2010) and to produce

outcome measurements for their practice. Descriptive measures are no longer considered satisfactory on their own, and Jennings (2011) advocates the use of such assessment and evaluation measures as the PASAA technique (Play and Story Attachment Assessment), among others. The big challenge facing those who engage in drama interventions is to consolidate the relationship between research, impact, and evidence (Jones 2012). Despite the wider debate about the efficacy of double-blind randomized controlled trials (RCTs) which are regarded as the gold standard in the generation of knowledge, Zeisel (2011) argues that they are only one way of representing knowledge and that there are other methodologies which contribute substantially to our knowledge of non-pharmacological interventions which need to be taken seriously. He includes in this list music, visual arts, film, drama, counseling, and storytelling and advocates that the most appropriate methodology is the one which best fits the research question. The challenge then for the field of drama interventions is to grow its practice-based research and increase capacity in different ways, as is occurring in other creative interventions, such as music, arts, and dance therapy (Jones 2012).

A significant stumbling block may be the lack of assessment instruments capable of adequately measuring social skills across a variety of contexts. Standardized tests are typically inadequate in sensitivity measures to assess these skills. Casson (2004) notes that while clients and participants may evaluate a session as being fun or enjoyable, clinical effectiveness demands measurement in terms of behavioral change and adjustments to societal norms (Jones 2012). While it is undeniable that more rigorous research designs and targeted evaluation of social skills are needed to determine the efficacy of drama interventions, a number of studies have relied on qualitative methodologies from the field of social sciences, which have yielded satisfactory results (Kempe and Tissot 2012; Trowsdale and Haythorne 2013). Most use instruments from play therapy and social communication interventions (Wolfberg et al. 2012; Lerner et al. 2011; Corbett et al. 2011), with the most popular measures in

drama therapy being the Strengths and Difficulties Questionnaire (SDQs), the CORE system (Clinical Outcomes for Routine Evaluation), Behavioral Summarized Evaluation, and Therapy Outcomes. More recently, PSYCHLOPS and PSYCHLOPS Kids have been successfully used with children with ASD as a reliable and highly sensitive measure of change during psychotherapeutic drama interventions (Godfrey and Haythorne 2013).

Qualifications of Treatment Providers

While there is currently no requirement for people who use drama interventions with people with ASD to be certified, the available evidence suggests that most are either trained actors or qualified elementary or high school teachers with experience of working in inclusive educational settings. Many have graduate qualifications in developmental psychology, drama, or theater in education, special education, autism studies, film and media studies, occupational therapy, speech and language therapy, and music and arts therapy. Guli et al. (2008) advocate for training not only in working with youth with ASD but also in understanding the specialized skills needed to facilitate drama interventions to achieve specific group and individual goals.

In contrast, drama therapy is a registered and licensed profession in the USA and UK. However, there is no state regulation currently in respect of drama or other arts therapies in many countries (see <http://www.dramatherapy.net> and <http://www.ecarte.info>). Drama therapy is a masters-level profession, with applicants having successfully pursued a bachelors degree in drama or a psychological health-related subject, with appropriate experience of working, paid or voluntarily, with people with specific needs, for example, mental ill health, learning disabilities, nursing assistant, support worker, and drama or theater work with people with specific needs. Course content typically covers such areas as psychology; drama, theater, and performance work; knowledge of related therapies such as art, music, dance/movement, and play; supervised drama

therapy practice; personal therapy parallel with training; supervised internship; and work experience. Registered drama therapists follow a code of ethics and abide by the professional body's regulations on fitness to practice, continuing professional development, and standards of proficiency.

Driving Hazard Perception in ASD

Elizabeth Sheppard and Danielle Ropar
School of Psychology, University of Nottingham,
Nottingham, UK

Synonyms

Situation awareness

Definition

Driving hazard perception is the ability to identify potentially dangerous events on the roads. It is typically tested by presenting participants with a series of video clips containing driving hazards filmed from the point of view of a driver. Participants are asked to press a button whenever they see a hazard developing and their accuracy and reaction time in doing so is measured. Hazard perception testing is based on the premise that the earlier a developing hazard is perceived, the longer the driver has for making a response, such as steering out of the way or slowing down; and consequently, the less likely an accident will occur. In line with this, hazard perception reaction time as measured in video-based hazard perception tests has been found to predict drivers' on-road accident involvement. In light of this, a hazard perception test of this nature is used as part of driver licensing procedures in addition to the on-road test in several countries including the UK, the Netherlands, and Australia.

Successful hazard perception frequently involves predicting the behavior of other road users. However, behavioral prediction has been reported as problematic for people with ASD (Zalla et al. 2010), raising the question of whether individuals with ASD have difficulty with hazard perception. Some research addressing this question has focused on individuals who have not yet started learning to drive to assess baseline levels of hazard perception skill,

Draw-a-Person Intellectual Ability Test for Children, Adolescents, and Adults

► Human Figure Drawing Tests

using the video-based testing methodology (Sheppard et al. 2010). Participants with ASD tended to be slower at responding to hazards than comparison individuals, and this appears to be due to those with ASD being slower in visually orienting to hazards within the driving scenes, perhaps due to less efficient search strategies (Sheppard et al. 2017). Non-drivers with ASD may also have poorer hazard perception accuracy (i.e., detect fewer hazards overall in such tests) than non-drivers without the condition, particularly when the hazard in question arises from the actions of a clearly visible person (Sheppard et al. 2010). This may relate to the well-documented difficulties attending to and processing dynamic social stimuli in ASD (e.g., Speer et al. 2007).

Research has also investigated hazard perception skill in experienced drivers with ASD using simulator driving, rather than a video-based hazard perception test (Bishop et al. 2017). In this context, the participant was not specifically asked to search for hazards but rather to complete a single simulator drive, during which several hazardous events were pre-programmed to occur at specific points. Hazard perception ability was indexed by measures of how the participant responded when the hazardous events occurred – such as by braking or steering. Drivers without ASD responded faster to hazards that involved a clearly visible person than hazards which did not, while drivers with ASD did not show this effect. However, overall there were few differences between the groups in how they responded to the hazardous events, implying that those with ASD who do drive may have similar hazard perception abilities to drivers without ASD.

While current drivers with ASD demonstrate hazard perception skills commensurate with comparison individuals, the differences in hazard perception skill in non-drivers with ASD might indicate additional challenges in learning to drive for individuals with ASD – especially in countries where hazard perception testing forms a mandatory part of driver licensing. Future research should examine

hazard perception in current learners with ASD to shed light on how hazard perception ability develops in this population during driver tuition.

[Diagnosis](#)

Definition

The Diagnostic and Statistical Manual (DSM), published by the American Psychiatric Association (APA), is widely used to diagnose psychopathology. The fifth edition of the DSM was published in May of 2013. The DSM-5 differs from its predecessor in that the manual is organized developmentally, beginning with disorders that are present early in life to disorders that are present later in life, rather than a multiaxial system. Autism spectrum disorder (ASD) is in the category of neurodevelopmental disorders. In the previous version of the DSM, ASD was an umbrella term used to house five distinct disorders: autistic disorder, Asperger's syndrome, childhood degenerative disorders, Rett's disorder, and pervasive developmental disorder not otherwise specified. In the current addition, Rett's disorder was completely removed, and the four remaining disorders collapsed into one ASD diagnosis. The rationale behind this change was that one single spectrum better exemplifies the symptoms, course, and treatment of the disorder. Additional changes included combining the socialization domain and the communication domain into one domain; the age of onset criterion was expanded to include early childhood in general, and the number of symptoms required to be met for diagnosis was made stricter.

To meet criteria for ASD, three of three criteria must be met in the social and communication deficits domain (i.e., nonverbal communication, peer relationships, and social reciprocity); two of four criteria must be met in the restricted and repetitive patterns of behavior, interest, and activities domain (i.e., stereotyped or repetitive movements, insistence on sameness, restricted or fixated interests, and hyper- or hyporeactivity to sensory input); symptoms must present early in the developmental period; and symptoms must cause clinically significant impairments. Diagnosis severity is indicated with levels: level one, "requiring support"; level two, "requiring substantial support"; and level three "requiring very substantial support." Medical conditions, intellectual impairments, and language impairments are

recorded as specifiers accompanying the disorder. Comorbid diagnoses which are not part of the ASD diagnostic criteria may be given along with the ASD diagnosis (e.g., ADHD, anxiety disorder, depression; APA 2013).

The changes to the ASD category of DSM-5 have been controversial and met with much resistance. Major concerns have been that the stricter criteria requirements will impact prevalence rates. Some researchers have estimated approximately 30–45 % of individuals currently diagnosed with an ASD will no longer meet criteria under the DSM-5 diagnosis, with those diagnosed with PDD-NOS most likely affected (Matson et al. 2012a, b; McPartland et al. 2012). Loss of diagnosis due to the diagnostic criteria changes will have a significant impact on services and eligibility. To address this concern, DSM-5 makes note that any individuals with an existing diagnosis will not lose existing services if they do not meet the new diagnostic criteria.

DSM-5 and Autism Spectrum Disorder

Isaac C. Smith

Department of Psychology, Virginia Polytechnic Institute and State University, Blacksburg, VA, USA

Definition

The Diagnostic and Statistical Manual of Mental Disorders, fifth edition, outlines diagnostic criteria for accepted mental disorders and is used in the United States to provide diagnostic codes for treatment. With regard to autism, the current edition of the DSM states that ASD is characterized by persistent deficits in social communication and social interaction across multiple contexts as well as the presence of restricted and repetitive patterns of behavior. Social communication deficits include deficits in social-emotional reciprocity, deficits in nonverbal communicative behaviors, and deficits in the development and maintenance of social relationships. Restricted and repetitive behaviors may include stereotyped motor movements, insistence on sameness, highly restricted interests, or hyper- or hyposensitivity to sensory input. The abovementioned symptoms must be present in the early developmental period in order to merit a diagnosis of ASD.

Historical Background

The first descriptions of the symptoms now collectively known as autism spectrum disorder (ASD) were provided by Kanner (1943) and Asperger (1944). Kanner reported on 11 children who demonstrated an “inability to relate themselves” to others and an “extreme autistic aloneness,” as well as resistance to environmental change (p. 242). One year later, Asperger published a similar description of social isolation, though in a sample of individuals with

substantially greater verbal abilities and interests in highly specialized topics (1944). Subsequent research identified additional individuals with similar constellations of symptoms, separated autism from established disorders such as schizophrenia, and identified a strong genetic component to the disorder due in part to high rates of seizures in individuals with ASD.

As the constellation of symptoms associated with autism became increasingly distinct, researchers began to define its symptoms more clearly. Preliminary efforts to provide specific diagnostic criteria for what is now termed ASD included a definition provided by the National Society for Autistic Children in 1977. These criteria included disturbances in rate of development, abnormal responses to sensations, delayed speech and language, and abnormal ways of relating to people, objects, or events (Ritvo and Freeman 1977). Autism was first included in the DSM with the publication of its third edition, which focused its criteria on “classic autism” and individuals with more severe impairments. Additionally, in order to qualify for a diagnosis, an individual was required to meet all specified criteria (APA 1980). Subsequent revisions introduced more developmentally oriented criteria and became more inclusive for individuals without cognitive deficits.

Autism spectrum disorders changed again with the publication of DSM-IV-TR in 2000. These new criteria were instrumental in facilitating an explosion of research focused on autism spectrum disorders. Despite this virtue, however, these criteria were subject to some notable shortcomings. The category of pervasive developmental disorders included autistic disorder, Asperger’s disorder, and pervasive developmental disorder—not otherwise specified (APA 2000). These three diagnoses allowed for useful distinctions among individuals with varying levels of impairment but also raised questions regarding differential diagnosis and whether “high-functioning autism,” Asperger’s disorder, and PDD-NOS were phenotypically distinct (South et al. 2005). Additionally, some evidence indicated that clinicians used the “not otherwise specified” diagnosis (PDD-NOS)

too broadly and that this diagnosis became a catch-all term for symptoms approaching, but not sufficient for, a diagnosis of Asperger's disorder or autistic disorder (Norbury 2014).

Current Knowledge

The DSM-5 neurodevelopmental disorders workgroup aimed to address many of the noted shortcomings of DSM-IV-TR criteria (APA 2013). The most salient change eliminated the previous category of pervasive developmental disorders and eliminated diagnoses of Asperger's disorder and PDD-NOS in favor of subsuming all autism diagnoses under the ASD label. Another notable difference was the reduction in symptom categories from three domains (i.e., social impairments, communication deficits, and restricted and repetitive behaviors) to two (i.e., social communication and restricted and repetitive behaviors). This change reflected acknowledgment by the workgroup that the distinction between the social and communication symptom domains was somewhat arbitrary and that both were reflective of core deficits attributable to autism (Lord and Jones 2012). Reducing the number of domains, and requiring that all three criteria within the social communication domain were met, greatly reduced the number of symptom combinations that could result in a diagnosis (Volkmar and Reichow 2013). Within the restricted and repetitive behaviors domain, an additional criterion regarding hyper- or hypo-reactivity to sensory stimuli was added. The final substantial change consisted of the addition of a severity specifier, in which individuals are classified as requiring very substantial support, requiring substantial support, or requiring support. These specifiers may provide a means of describing an individual and their needs with a greater level of detail given that new criteria render it possible for individuals of widely varying levels of symptoms and cognitive ability to receive the same diagnosis. The extent to which these severity specifiers will affect research or clinical work remains unclear. Members of the neurodevelopmental disorders workgroup

conducted a detailed analysis of sensitivity and specificity of the finalized new criteria and found compelling evidence to suggest that the vast majority of individuals with DSM-IV-TR PDD diagnoses would retain them under the new criteria and that specificity improved markedly (Huerta et al. 2012).

As published, DSM-5 criteria offered advantages to the old classification system and accomplished stated goals of the neurodevelopmental disorders workgroup. However, a series of studies conducted in the period leading up to and immediately following publication suggested that the new criteria may be problematic in a number of ways. Among the most prominent of these examinations consisted of reevaluation of data collected on nearly 1000 individuals during the field trial for development of DSM-IV criteria. Clinicians reevaluated each case according to the proposed DSM-5 criteria; results suggested that only 60% of individuals classified with ASD under DSM-IV-TR criteria would receive diagnosis when assessed according to proposed DSM-5 criteria (McPartland et al. 2012). Reported specificity, however (i.e., correct identification of individuals who do *not* have ASD), was excellent (95%). A number of additional studies were published demonstrating similar effects of the proposed new criteria. Mattila et al. (2011) found a similarly low sensitivity of new criteria in conducting an epidemiological study of children in Finland.

Results of both of these studies also suggested that certain subsets of the ASD population would be disproportionately affected by these changes. Individuals diagnosed with Asperger's disorder or PDD-NOS under DSM-IV-TR criteria as well as individuals without intellectual disability (i.e., IQ >70) were more likely to fail to meet diagnostic criteria per DSM-5 than those with autistic disorder or intellectual disability. Other studies found similar reductions in the number of overall individuals diagnosed using the new criteria (Matson et al. 2012b). Analyses of samples of individuals meeting versus not meeting DSM-5 criteria suggested that individuals meeting DSM-5

criteria represented a more impaired population with higher levels of core symptoms than those meeting DSM-IV-TR, but not DSM-5, criteria (Matson et al. 2012a).

Reviews and meta-analyses of studies exploring changes in rates of ASD diagnoses based on DSM-5 criteria presented substantial evidence that considerable numbers of individuals would fail to qualify for diagnoses under new criteria and that individuals with high IQs and those previously diagnosed with Asperger's or PDD-NOS would be disproportionately affected (Kulage et al. 2014; Sturmey and Dalfern 2014; Smith et al. 2015). This evidence, however, must be considered along with a number of notable limitations. The majority of the studies described above relied on retrospective data, collected prior to the development and proposal of DSM-5 criteria. As a result, available data did not allow for comprehensive assessment by new criteria, potentially affecting reported sensitivity and specificity.

Publication of the studies described above resulted in considerable concern within the ASD research community. Changes in the set of symptoms considered under the ASD label created a number of potential difficulties with the application of criteria, both in research and clinical practice. If the population of individuals characterized as having ASD under DSM-5 differed substantially from those diagnosed with a disorder under the ASD umbrella in DSM-IV-TR, prior research conducted on the latter group might have limited application to individuals with a different constellation of symptoms (i.e., generally more severely affected). Questions regarding application of the new criteria also arose with regard to clinical practice and access to services. Prior to official publication, the proposed criteria made it theoretically possible for an individual diagnosed with autistic disorder, Asperger's, or PDD-NOS to fail to qualify for a diagnosis under the new criteria, potentially limiting that individual's access to treatment and support services. As a result, a stipulation was added to DSM-5 criteria stating that any individual qualifying for a diagnosis under DSM-IV-TR would automatically be

assigned the label of ASD under DSM-5, regardless of whether or not the new criteria were met.

While providing a single label for all autism spectrum disorders clarified distinctions among diagnostic subtypes and increased parsimony in the ASD research community, the effects of these terminology changes on individuals with ASD and their families may be considerable. First, families who have not kept abreast of changes within the research community were likely unaware that the label assigned to a given individual may have changed with the publication of DSM-5 (e.g., an individual with Asperger's now technically meriting a diagnosis of ASD). This offers the potential for confusion when families seek assessment or treatment, as providers are likely to have shifted in their usage of terminology with the publication of the new criteria, while families continue to use DSM-IV-TR labels. Second, and perhaps more importantly, new terminology may be unwelcome or even offensive to communities of individuals who identified strongly with previously used labels. Specifically, some individuals with Asperger's have demonstrated a strong affiliation with that term and its variants. This term and others have been used by the neurodiversity movement, which advocates against pathologizing ASD, especially by the scientific community; instead, they aim to characterize ASD as a different manner of thinking and not as a "disorder" *per se* (Robertson and Ne'eman 2008).

Another substantial change to the neurodevelopmental disorders section of the DSM in its fifth edition was the addition of social (Pragmatic) communication disorder (SCD). SCD is closely related to ASD in that its diagnosis requires deficits in the use of communication for social purposes, including social pragmatics and turn-taking (APA 2013). However, notably absent from diagnostic criteria is the presence of restricted and repetitive behaviors. The SCD diagnosis should be considered here as a new, independent neurodevelopmental disorder with a unique phenotype and associated symptoms.

However, this new diagnosis should also be viewed within the context of the debate surrounding new DSM criteria. Some researchers have

suggested that SCD, with a symptom set more limited than ASD, will occupy the same role in diagnosis that PDD-NOS did in DSM-IV-TR (i.e., essentially a milder form of autism). In this manner, the SCD diagnosis would constitute somewhat of a catch-all, and its validity could be called into question. Others have proposed that SCD should be considered in relation to the substantial number of individuals who may “lose” diagnoses in the transition from DSM-IV-TR to DSM-5. The possibility exists that individuals no longer meeting full criteria for ASD would be found not to meet criteria only in the restricted and repetitive behavior domain, and thus these individuals would be diagnosed with SCD. A final point to be made regarding SCD is that there exists some question regarding whether or not SCD can be considered a distinct phenotype, that is, whether it is possible that social pragmatic communication deficits appear in the absence of accompanying restricted and repetitive behaviors (Norbury 2014). As this diagnosis becomes more solidified with their application in research and clinical practice, the field will approach answers to these questions, as well as begin to identify appropriate services and interventions for individuals in this population.

Future Directions

Despite the controversy and limitations described above, DSM-5 criteria for ASD are, and will remain, the current valid and accepted criteria for ASD. Despite the increasing period of time that has passed since the publication of the new criteria, researchers have continued to examine the application of the criteria in new or different settings and question their utility (e.g., Bent et al. 2017). Although there exists substantial evidence to support modification of the current criteria to remedy some of the documented shortcomings of DSM-5 criteria, changes appear unlikely. Criteria published in previous versions of the DSM have also resulted in disagreement among the scientific community, and disputes arising from their publication did not serve to limit progress in ASD

research in any substantial way; DSM-5 criteria are not likely to represent a unique case.

Although future versions of the DSM may improve upon current criteria and allow for more accurate, sensitive, and specific diagnoses of ASD at earlier ages, the inherent limitations of behavioral criteria in diagnosing a neurodevelopmental disorder suggest that the ultimate goal must be a reliable and valid biomarker that can be used to diagnose ASD, even prior to the emergence of behavioral symptoms. A number of potential biological indicators predictive of diagnosis of ASD have been explored. Identification of biomarkers would be beneficial as a means of objective diagnosis but also in the ability of researchers to objectively measure treatment response. Neuroimaging techniques such as fMRI have also been considered as a potential means of making more objective diagnoses. The use of biomarkers is an emerging research area, with ongoing multisite trials contributing to significant advances. Recent evidence suggests that hyperexpansion of the cortical surface area in infants between 6 and 12 months of age was associated ASD diagnoses later in life (Hazlett et al. 2017). This and other emerging evidence suggests that the use of biomarkers for diagnosis offers considerable advantages over current behavioral criteria. Despite these advances, identification of clear and objective biomarkers that could be easily applied (i.e., low-cost and widely available) is likely too distant to consider as the next step in diagnosis of ASD. Future revisions of DSM-5 will likely update diagnostic criteria to remain current with advances in research providing a clearer conceptualization of symptoms that constitute ASD.

DSM-III

Fred R. Volkmar

Child Study Center, Irving B. Harris Professor of Child Psychiatry, Pediatrics and Psychology, Yale Child Study Center, School of Medicine, Yale University, New Haven, CT, USA

Definition

The 3rd edition of the *American Psychiatric Association's Diagnostic and Statistical Manual* (DSM-III) appeared in 1980 and proved to be a landmark in the development of psychiatric taxonomy.

Historical Background

Beginning in the 1800s, attempts had begun to be made in categorizing and studying rates of various disorders (including psychiatric disorders) in the USA and other countries. For psychiatry, an attempt was made to codify a specific approach in the early 1900s and was subsequently revised. These early attempts included only a small of categories. However, following World War II, a concern for providing mental health services in a more systematic fashion (and including to the many returning veterans) provided a stimulus for the first edition of DSM. This effort reflected both a growing awareness of the mental health issues in the military in the USA and the stimulus provided by a revision (the 6th edition) of the *International Statistical Classification of Diseases* (ICD) which recognized mental disorders for the first time. A second edition was undertaken in the 1960s, and DSM-II recognized over 180 disorders. Both the first and second editions of DSM adopted a specific theoretical (e.g., psychodynamic) framework. Developments more broadly in the field (particularly at Washington University in St. Louis and subsequently at Columbia University) led to a focus on less theoretical and more descriptive definitions useful for research. This research diagnostic criteria approach (Spitzer

et al. 1978) proved particularly helpful, and the decision was made for the third edition of DSM to move toward such an approach as well as greater convergence with the ICD (Spitzer et al. 1978).

Current Knowledge

Changes were made in DSM-III based on a series of consideration including issues of reliability and results of “field trials.” By the time it was published in the 1980s, DSM-III included over 260 categories and quickly proved invaluable in transforming research in psychiatry. Although not without controversy (e.g., around use of terms like neurosis and the approach to diagnosis of sexual orientation problems) for childhood-onset disorders, DSM-III had several important advantages. It recognized disorders like autism for the first time (previously the term childhood schizophrenia was the only “official” diagnosis available) based on a series of papers in the 1970s demonstrating the unique diagnostic features and course of children with autism (Kolvin 1971; Rutter 1972). Autism was included along with several other disorders in a newly class of conditions – the pervasive developmental disorders (PDD). Disorders recognized within this class included infantile autism, residual infantile autism (for individuals who once met full criteria for the infantile form of the disorder), childhood-onset pervasive developmental disorder (COPDD) (to encompass the rare individuals who developed autism or something very like it after several years of normal development), and a residual COPDD category along with a new subthreshold condition atypical PDD. The class name *pervasive developmental disorder* was used to refer to what today might more usually be termed autism spectrum disorders. The PDD term was meant to convey that a range of functions were impacted, although the term itself was widely debated (e.g., see Gillberg 1991; Volkmar and Cohen 1991b).

Apart from the explicit recognition of autism as a specific and valid diagnostic category, the DSM-III had several important advantages for childhood disorders in general including the use of multiple axes of diagnosis (psychiatric,

developmental, medical, and psychosocial stressors and overall adaptive functioning). This multiple axial approach proved especially helpful for child psychiatry (Rutter et al. 1975). The use of more detailed and specific definitions without a specific theoretical bias also enhanced reliability. The *DSM-III* system also had some disadvantages for autism. The proposed was based largely on Rutter's modification (Rutter 1978) of Kanner's (1943) original description, but in the attempt to make this more operational, the monothetic definition adopted focused on what might now be thought of as more prototypical ("classical") autism, i.e., more "infantile" autism (consistent with the name chosen). For example, the social criterion emphasized a pervasive lack of social responsiveness. This effectively meant that for many children who developed (to varying degrees) greater social skills, the clinician was technically forced to use the "residual" autism category. A problem with this lack of developmental orientation was the implicit implication that somehow their problems were less severe. Similarly, the rationale for COPDD as a category was to account for the small number of children who had developed an autistic-like disorder at a somewhat later point in early childhood (Kolvin 1971); COPDD was not, however, meant to be simply with Heller's syndrome (disintegrative psychosis) (Heller 1908, 1930) as it was assumed, probably incorrectly, that the latter was invariably a result of a general medical/neurological process (see Volkmar and Rutter 1995). Similarly, the term *atypical PDD* was used as a placeholder for the subthreshold condition ("autistic-like" or now "autism spectrum disorder") for difficulties that appeared to be best thought of as occurring within the overarching PDD class but meeting criteria for infantile autism or COPDD. Unfortunately, this term had its own prior history in that it was suggestive of Rank's earlier concept of atypical personality (Rank 1949; Rank and MacNaughton 1949). Another problem arose because of the recognition that autism was *not* a kind of schizophrenia and the adoption of an exclusionary rule for autism and schizophrenia; on the other hand, one might reasonably argue that adolescents and adults with autism are not necessarily protected

from this condition in later life – at rates presumably at least comparable to those of the general population (Volkmar and Cohen 1991b). Finally the multi-axial placement of autism and related disorders was somewhat controversial. Autism and mental retardation (intellectual disabilities) were by convention made axis I diagnosis, while the specific developmental disorders were placed on axis II of the multi-axial system. The problems with *DSM-III* were widely recognized, and a major revision was undertaken for *DSM-III-R* (American Psychiatric Association 1980, 1987).

DSM-III-R

Fred R. Volkmar

Child Study Center, Irving B. Harris Professor of Child Psychiatry, Pediatrics and Psychology, Yale Child Study Center, School of Medicine, Yale University, New Haven, CT, USA

Definition

The successor to DSM-III (appearing in 1987) work on this edition began shortly after DSM-III (1980) had appeared. Originally viewed as a small-scale revision, major changes were made in several categories including autism and related conditions (see Waterhouse et al. 1993). The definition of autistic disorder (name changed from infantile autism in DSM-III) was more consistent with the views of Lorna Wing and her colleagues (e.g., see Wing 1981) who adopted a somewhat broader diagnostic view of the concept. This revision also put much greater weight on developmental changes discarding the earlier concept of “residual” infantile autism and replacing it with a single category with criteria applicable to the entire range of functioning over age and developmental level. Consistent with the previous

definition, the three major domains of dysfunction (social, communicative, and restricted interests/behaviors) were included, although early age of onset was no longer required. Final scoring rules were developed based on a field trial (Spitzer and Siegel 1990) with 16 criteria; a diagnosis of autism required that an individual exhibited at least 8 of these features (with a specified distribution over the 3 areas). The problematic earlier concept of childhood-onset pervasive developmental disorder (COPDD) was dropped, and throughout the manual, the earlier term “atypical” was replaced with “not otherwise specified” (in large part because of the potential confusion with an earlier diagnostic concept – atypical personality development; see (Volkmar and Klin 2005)).

The greater developmental orientation of the approach was welcomed but also appeared to come at a price. Several reports suggested high rates of false positives – particularly relative to more intellectually disabled individuals; this led to an apparent overdiagnosis of autism in more intellectually handicapped individuals while also diverting attention from more cognitively able persons. Additional problems included a complex and detailed criteria set with inclusion of examples within criteria (thus tending to “reify” the examples as features that should be present). The changes introduced complicated interpretation of previous research and were particularly acute relative to pending changes in the ICD (see Volkmar and Klin 2005; Volkmar et al. 1992).

DSM-IV

Fred R. Volkmar

Child Study Center, Irving B. Harris Professor of Child Psychiatry, Pediatrics and Psychology, Yale Child Study Center, School of Medicine, Yale University, New Haven, CT, USA

Definition

The fourth edition of the *American Psychiatric Association's Diagnostic and Statistical Manual* was published in 1994 with a subsequent text revision published in 2000. The publication of DSM-IV followed several years of preparation. For autism and related disorders, the definitions proposed were, for the first time, convergent with the International Classification of Diseases 10th Edition (ICD-10). The fourth edition marked some important changes from its predecessors while maintaining much in the way of historical continuity.

Historical Background

Preparations for the fourth edition of DSM began shortly after DSM-III-R (APA 1987) due, in part, to the pending revision of ICD-10, and this edition

appeared partly due to the pending changes in the ICD-10. The intention was to base the revision on research and with consideration of relevant issues such as clinical utility, reliability, and descriptive validity of categories and the issue of coordination with ICD-10 (WHO 1994). As part of this process, a series of literature reviews were conducted with emphasis on categories “new” to DSM. On balance, these reviews suggested the potential usefulness of including categories in addition to autism within the overarching pervasive developmental disorder (PDD) group (see Volkmar and Klin (2005)) and also supported the desire for compatibility with ICD-10. As part of this process, a series of data reanalyses that were undertaken focused on autism, and these suggested the DSM-III-R definition to be overly broad (Volkmar et al. 1992). Other issues identified included the inclusion (or not) of early age of onset as an essential feature and the variability of sensitivity/specificity in relation to IQ and other variables, and to address these concerns, a large, international field trial was undertaken in conjunction with ICD-10.

Current Knowledge

The DSM-IV Field Trial

The final DSM-IV definition was based on the results of the DSM-IV field trial which included 21 sites from around the world, over 100 raters, and nearly 1,000 cases (Volkmar et al. 1994). Cases were sometimes rated more than once (for reliability), and other issues (e.g., rater experience) were addressed. In general, cases were rated as seen over the course of a year but with some supplementation of previously seen cases for certain issues (e.g., children with “late-onset” autism). Cases could be included if the clinician believed autism to reasonably be part of the differential diagnosis. Multiple sources of information (assessment, history) were available to the raters who judged the quality of data available to them good or excellent about 75% of the time. A standard coding system was used with information on the case and rater as well as ratings of various diagnostic criteria. The DSM-III approach

DSM-IV, Table 1 ICD-10 criteria for autism and related pervasive developmental disorders

Childhood autism (F84.0)	
(A) Abnormal or impaired development is evident before the age of 3 years in at least one of the following areas:	1. Receptive or expressive language as used in social communication
	2. The development of selective social attachments or of reciprocal social interaction
	3. Functional or symbolic play
(B) A total of at least six symptoms from (1), (2), and (3) must be present, with at least two from (1) and at least one from each of (2) and (3)	1. Qualitative impairments in social interaction are manifest in at least two of the following areas:
	(a) Failure adequately to use eye-to-eye gaze, facial expression, body postures, and gestures to regulate social interaction
	(b) Failure to develop (in a manner appropriate to mental age, and despite ample opportunities) peer relationships that involve a mutual sharing of interests, activities, and emotions
	(c) Lack of socio-emotional reciprocity as shown by an impaired or deviant response to other people's emotions; or lack of modulation of behavior according to social context; or a weak integration of social, emotional, and communicative behaviors
	(d) Lack of spontaneous seeking to share enjoyment, interests, or achievements with other people (e.g., a lack of showing, bringing, or pointing out to other people objects of interest to the individual)
	2. Qualitative abnormalities communication as manifest in at least one of the following areas:
	(a) Delay in or total lack of development of spoken language that is not accompanied by an attempt to compensate through the use of gestures or mime as an alternative mode of communication (often preceded by a lack of communicative babbling)
	(b) Relative failure to initiate or sustain conversational interchange (at whatever level of language skill is present), in which there is reciprocal responsiveness to the communications of the other person
	(c) Stereotyped and repetitive use of language or idiosyncratic use of words or phrases
	(d) Lack of varied spontaneous make-believe play or (when young) social imitative play
	3. Restricted, repetitive, and stereotyped patterns of behavior, interests, and activities are manifested in at least one of the following:
	(a) An encompassing preoccupation with one or more stereotyped and restricted patterns of interest that are abnormal in content or focus, or one or more interests that are abnormal in their intensity and circumscribed nature though not in their content or focus
	(b) Apparently compulsive adherence to specific, nonfunctional routines or rituals
	(c) Stereotyped and repetitive motor mannerisms that involve either hand or finger flapping or twisting or complex whole-body movements
	(d) Preoccupations with part objects or nonfunctional elements of play materials (such as their odor, the feel of their surface, or the noise or vibration they generate)

(continued)

DSM-IV, Table 1 (continued)

(C) The clinical picture is not attributable to the other varieties of pervasive developmental disorders; specific development disorder of receptive language (F80.2) with secondary socio-emotional problems' reactive attachment disorder (F94.1) or disinhibited attachment disorder (F94.2); mental retardation (F70-F72) with some associated emotional or behavioral disorders; schizophrenia (F20) of unusually early onset; and Rett's syndrome (F84.12)	
F84.1 Atypical autism	
A pervasive developmental disorder that differs from autism in terms <i>either</i> of age of onset <i>or</i> of failure to fulfill all three sets of diagnostic criteria. Thus, abnormal and/or impaired development becomes manifest for the first time only after age 3 years, and/or there are insufficient demonstrable abnormalities in one or two of the three areas of psychopathology required for the diagnosis of autism (namely, reciprocal social interactions, communication, and restrictive, stereotyped, repetitive behavior) in spite of characteristic abnormalities in the other area(s). Atypical autism arises most often in profoundly retarded individuals whose very low level of functioning provides little scope for exhibition of the specific deviant behaviors required for the diagnosis of autism; it also occurs in individuals with a severe specific developmental disorder of receptive language. Atypical autism thus constitutes a meaningfully separate condition from autism and includes: Atypical childhood psychosis Mental retardation with autistic features	
F84.1 Atypical autism	(A) Abnormal or impaired development is evident at or after the age of 3 years (criteria as for autism except for age of manifestation) (B) There are qualitative abnormalities in reciprocal social interaction or in communication, or restricted, repetitive, and stereotyped patterns of behavior, interests, and activities (criteria as for autism except that it is unnecessary to meet the criteria for number of areas of abnormality) (C) The disorder does not meet the diagnostic criteria for autism (F84.0). Autism may be atypical in either age of onset (F84.10) or symptomatology (F84.11); the two types are differentiated with a fifth character for research purposes. Syndromes that are typical in both respects should be coded F84.12
F84.10 Atypicality in age of onset	(A) The disorder does not meet criterion A for autism (F84.0); that is, abnormal or impaired development is evident only at or after age 3 years (B) The disorder meets criteria B and C for autism (F84.0)
F84.11 Atypicality in symptomatology	(A) The disorder meets criterion A for autism (F84.0); that is, abnormal or impaired development is evident before age 3 years

(continued)

DSM-IV, Table 1 (continued)

	(B) There are qualitative abnormalities in reciprocal social interactions or in communication, or restricted, repetitive, and stereotyped patterns of behavior, interests, and activities (criteria as for autism except that it is unnecessary to meet the criteria for number of areas of abnormality)
	(C) The disorder meets criterion C for autism (F84.0)
	(D) The disorder does not fully meet criterion B for autism (F84.0)
F84.12 Atypicality in both age of onset and symptomatology	(A) The disorder does not meet criterion A for autism (F84.0); that is, abnormal or impaired development is evident only at or after age 3 years
	(B) There are qualitative abnormalities in reciprocal social interactions or in communication, or restricted, repetitive, and stereotyped patterns of behavior, interests, and activities (criteria as for autism except that it is unnecessary to meet the criteria for number of areas of abnormality)
	(C) The disorder meets criterion C for autism (F84.0)
	(D) The disorder does not fully meet criterion B for autism (F84.0)

Source: World Health Organization (2003)

was noted to be developmentally less sensitive than DSM-III-R, although that system appeared to overdiagnose autism in individuals with more severe intellectual handicap (i.e., relative to clinician judgment). The ICD-10 draft approach appeared more reasonable although overly detailed. Reliability of criteria was generally good with clinical diagnosis also noted to have excellent reliability for more experienced clinicians (Klin et al. 2000). A series of analyses suggested that a modification of the draft ICD-10 approach could be adopted with reasonable sensitivity and specificity and good coverage over the IQ range.

Although not primarily focused on disorders other than autism, the field trial also provided data regarding the inclusion and definition of Asperger’s disorder, Rett’s disorder, and childhood disintegrative disorder. The final DSM-IV definition had good sensitivity and specificity

over the IQ range. Diagnostic criteria adopted were essentially the same as in ICD-10 (see Table 1). At least six criteria had to be rated positive for a diagnosis of autism with at least two of these from the “social” category (this was consistent with Kenner’s original view of autism and also with a series of data analyses that confirmed the importance of social features). At least one feature must be present from the other two groups (impaired communication/play and restricted interests). Onset before age 3 was also specified.

The inclusion of various condition as well as autism and “subthreshold autism” was a major change from DSM-III-R. Although the substantive work on these other conditions was less advanced than that for autism, there appeared to be sufficient data for their inclusion; this further enhanced compatibility with ICD-10. Convergence of the final ICD-10 and DSM-IV definitions

of autism represented a major shift (i.e., with the same system being used around the world) and facilitated subsequent research and clinical work as reflected, in part, in the explosion of work in the area over the subsequent decade. These criteria are provided in Table 1.

Future Directions

At the time of this writing, preparation for DSM-V was underway with the two major preliminary proposals suggesting a change of the class of disorder to autism spectrum disorder and collapsing the various disorders currently listed in DSM-IV within one overarching disorder type.

DSM-IV Field Trial

Fred R. Volkmar

Child Study Center, Irving B. Harris Professor of Child Psychiatry, Pediatrics and Psychology, Yale Child Study Center, School of Medicine, Yale University, New Haven, CT, USA

Definition

The DSM-IV field trial for autism (Volkmar et al. 1994) was an international effort with the goal of establishing a definition with a reasonable balance of sensitivity and specificity that could be used to facilitate both clinical work and research. In contrast to previous DSM definitions of autism, this effort was done in conjunction with the ICD-10 revision 21 sites and 125 raters participated from around the world.

Historical Background

The DSM-IV field trial arose as a result of concerns about the definition of autism adopted in DSM-III and DSM-III-R. For the latter definition, a small field trial had been conducted but suffered from some deficiencies. Several published papers suggested that while the DSM-III-R definition was more developmental in nature, it also appeared to be more likely to give an autism diagnosis to individuals with greater levels of intellectual disability.

Current Knowledge

This field trial followed a period of considerable work including targeted literature reviews and data reanalyses (e.g., Frances et al. 1991; Mayes et al. 1993; Szatmari 1991, 1992a, b; Tsai 1992; Volkmar 1991, 1992; Volkmar et al. 1992a, b).

As part of the field trial, 21 sites and 125 raters participated. Each site had some clinical program for individuals with autism and raters with a range of experience and professional backgrounds;

DSM-IV Field Trial, Table 1 DSM-IV autistic disorder field trial group characteristics*

	Clinically autistic (<i>N</i> = 454)	Other PDDs (<i>N</i> = 240)	Non-PDD (<i>N</i> = 283)
Sex ratio (M/F)	4.49:1	3.71:1	2.29:1
% mute	54%	35%	33%
Age	8.99	9.68	9.72
IQ	58.1	77.2	66.9

*Note: Cases grouped by clinical diagnosis
Diagnoses of the “other PDD” cases included: Rett’s syndrome (13 cases), childhood disintegrative disorder (16 cases), Asperger syndrome (48 cases), PDD-NOS (116 cases), and atypical autism (47 cases)
Diagnoses of the non-PDD cases included mental retardation (132 cases), language disorder (88 cases), childhood schizophrenia (9 cases), and other disorders (54 cases)
Adapted from Volkmar et al. (1994). Reprinted from Volkmar et al. Issues in classification, Chapter in F. Volkmar, A. Klin, R. Paul, & D. Cohen (Eds.), *Handbook of Autism and Pervasive Developmental Disorders*, Vol I, page

about half the rates report relatively extensive experience allowing for comparison of issues of reliability and clinical utility in both more and less experienced clinicians. Over the course of a year, nearly 1,000 cases were submitted (with about 10% of cases rated by more than 1 evaluator). In general, the preference was that bases currently being seen be provided (i.e., rather than ratings based on past experience), and by design, 5 of the participating sites contributed about 100 consecutive cases. To be included, the case had to exhibit difficulties in which autism was a reasonable part of the differential diagnosis. Smaller groups of cases were specifically solicited to identify potential gaps relative to much less frequent conditions (e.g., Rett’s and childhood disintegrative disorders). However, consecutive cases constituted the bulk of the sample. Typically multiple sources of information were available (e.g., parents, past records, as well as current assessment), and raters indicated that in the majority (75%) of cases, the information available was good or excellent.

A standard system of coding was created for each deidentified case rating including information on the individual being examined (age, IQ, communicative ability, educational placement), basic information on the evaluator(s), and explicit ratings of diagnostic criteria both from previous (DSM-III, III-R) and potential new criteria. The evaluator was also asked to provide his/her best judgment of clinical diagnosis – the latter serving as the “gold standard” against which comparisons would then be made. The rating form also provided possible criteria for

Asperger’s syndrome, Rett’s syndrome, and childhood disintegrative disorder, based on the draft ICD-10 definitions.

Sample information is presented in Table 1. Clinicians’ primary diagnosis of the “nonautistic” PDD cases included Rett’s syndrome (13 cases), childhood disintegrative disorder (16 cases), Asperger’s syndrome (48 cases), and PDD-NOS (116 cases) or atypical autism (47 cases) (the latter group was included as possible clinical diagnosis given the ICD-10 draft inclusion of such a category which, essentially, referred to “subthreshold” autism or autism that was atypical in somewhat – cases that in US terminology would have been said to have PDD-NOS). In comparison (nomad), cases with primary clinical diagnoses included mental retardation (*N* = 132), language disorder (*N* = 88 cases), schizophrenia of childhood onset (*N* = 9), and other or mixed developmental disorders (*N* = 54).

A series of cases were addressed in a range of different analyses, and in addition to the main report of the field trial (Volkmar et al. 1994), many of these analyses were published in their own right. Consistent with previous reports, it appeared that the DSM-III approach was insufficiently developmental and overly stringent, whereas the DSM-III-R erred on the site of over-diagnosis of autism associated with more severe intellectual deficiency. An explicit goal for the development of final criteria set was that the final criteria for autistic disorder should work reasonably well over the entire range of IQ. A result is more consistent with the much more

DSM-IV Field Trial, Table 2 Sensitivity/specificity by IQ level – a comparison of DSM-III^a DSM-III-R ICD-10^b

Overall		Se	Sp	Se	Sp	Se	Sp
		0.82	0.8	0.86	83	0.79	89
By IQ level	N	Se	Sp	Se	Sp	Se	Sp

^bOriginal ICD-10 criteria and scoring

detailed ICD-10 (research) draft definition. These results are presented in Table 2.

In looking at other sources of diagnostic disagreement, it appeared that DSM-III-R’s failure to include age of onset as an essential feature contributed to its difficulties, while, on the other hand, its great developmental orientation and flexibility appeared to be a plus. Indeed, if onset of the condition by age 3 years was included as an essential feature, the sensitivity of that system was increased.

The available data also allowed for examination of clinician agreement on diagnosis based on various factors including clinician experience. Using chance-corrected statistics, the inter-rater reliability of individual diagnostic criteria was examined and in the good to excellent range. Typically more detailed criteria had greater reliability. More experienced raters also had excellent reliability both on the broader autism spectrum and narrower autistic disorder diagnoses; this was much less true for inexperienced raters (see Klin et al. 2000). In addition to inter-rater reliability, temporal stability was examined in a small number of cases and generally high; diagnosis stability was more problematic for very young children, those with lower IQ, and with the DSM-III-R system.

Before a final decision could be made about the definition of autistic disorder in DSM-IV, it was important to decide whether other disorders would be included in the PDD class (see Szatmari

1992a, b; Tsai 1992; Volkmar 1992; Volkmar et al. 1992a). While these disorders were not a primary focus of the field trial, some data relevant to their inclusion had been collected. Data from the field trial supported the inclusion of these conditions (Asperger’s disorder, Rett’s disorder, and childhood disintegrative disorder), and their inclusion had some advantages relative to compatibility with ICD-10 and for deriving a better diagnostic approach for autistic disorder. One area of difference between ICD-10 and DSM-IV was left unresolved; this had to do with the concept of atypical autism vs. PDD-NOS. ICD-10 allowed for more detailed coding of the “atypicality” of the presentation, e.g., failing to meet age or specific criteria cutoffs, while DSM-IV adopted a broader view of this as a “subthreshold” category that, today, would be equated with autism spectrum disorder.

The field trial data suggested that age of onset as an additional feature would have strengthened the DSM-III-R definition. A series of alternatives were considered, and in the end, a final definition was developed in coordination with IDD-10 (see “Appendix”). This definition balanced clinical and research needs, was reasonably concise and user-friendly, and had good coverage over both age and developmental level.

Several changes in proposal for other categories (notably Asperger’s disorder and PDD-NOS) were made in the final stages of the DSM process; these have raised other issues of concern to the

field (e.g., see Buitelaar et al. 1999; Miller and Ozonoff 1997). Some of these concerns were addressed in the DSM-IV text revision, which appeared in 2000; for Asperger's disorder, the text was very extensively revised, although no changes in the formal criteria were made.

The rather extensive field trial undertaken for DSM-IV contrasts markedly from that used in DSM-5 and may explain, in part, the various problems with the latter's approach (Smith et al. 2015).

Appendix

ICD-10 Research Criteria*. Source: Diagnostic descriptions and criteria for autism and related pervasive developmental disorders from international classification of diseases, 10th Edition (World Health Organization, Geneva, Switzerland, 2003).

	<i>Pervasive developmental disorders</i>
	A group of disorders characterized by qualitative abnormalities in reciprocal social interactions and in patterns of communication and by a restricted, stereotyped, repetitive repertoire of interests and activities. These qualitative abnormalities are a pervasive feature of the individual's functioning in all situations.
	Use additional code, if desired, to identify any associated medical condition and mental retardation.
<i>F84.0</i>	<i>Childhood autism</i>
	A type of pervasive developmental disorder that is defined by (a) the presence of abnormal or impaired development that is manifest before the age of 3 years and (b) the characteristic type of abnormal functioning in all the three areas of psychopathology: reciprocal social interaction, communication, and restricted, stereotyped,

(continued)

	repetitive behavior. In addition to these specific diagnostic features, a range of other nonspecific problems are common, such as phobias, sleeping and eating disturbances, temper tantrums, and (self-directed) aggression.	
	Autistic disorder	
	Infantile	
	Autism	
	Psychosis	
	Kanner's syndrome	
	<i>Excludes:</i>	Autistic psychopathy (<i>F84.5</i>)
<i>F84.1</i>	<i>Atypical autism</i>	
	A type of pervasive developmental disorder that differs from childhood autism either in age of onset or in failing to fulfil all three sets of diagnostic criteria. This subcategory should be used when there is abnormal and impaired development that is present only after age 3 years, and a lack of sufficient demonstrable abnormalities in one or two of the three areas of psychopathology required for the diagnosis of autism (namely, reciprocal social interactions, communication, and restricted, stereotyped, repetitive behavior) in spite of characteristic abnormalities in the other area(s). Atypical autism arises most often in profoundly retarded individuals and in individuals with a severe specific developmental disorder of receptive language.	
	Atypical childhood psychosis	
	Mental retardation with autistic features	
	Use additional code (<i>F70-F79</i>), if desired, to identify mental retardation.	
<i>F84.2</i>	<i>Rett's syndrome</i>	
	A condition, so far, found only in girls, in which apparently normal early development is followed by partial or complete loss of speech and of skills in locomotion and use of hands, together with deceleration in head growth, usually with an onset between seven and 24 months of age. Loss of purposive hand movements, hand-wringing stereotypies, and hyperventilation are characteristic. Social and play development are arrested, but social interest tends to be maintained. Trunk ataxia and apraxia start to develop by age 4 years and choreoathetoid movements frequently follow. Severe mental retardation almost invariably results.	
<i>F84.3</i>	<i>Other childhood disintegrative disorder</i>	
	A type of pervasive developmental disorder that is defined by a period of entirely normal development before the onset of the disorder, followed by a definite loss of previously acquired skills in several areas of development over the course of a few months.	

(continued)

	Typically, this is accompanied by a general loss of interest in the environment, by stereotyped, repetitive motor mannerisms, and by autistic-like abnormalities in social interaction and communication. In some cases the disorder can be shown to be due to some associated encephalopathy, but the diagnosis should be made on the behavioral features.
	Dementia infantilis
	Disintegrative psychosis
	Heller's syndrome
	Symbiotic psychosis
	Use additional code, if desired, to identify any associated neurological condition.
	<i>Excludes:</i> Rett's syndrome (F84.2)
F84.4	<i>Overactive disorder associated with mental retardation and stereotyped movements</i>
	An ill-defined disorder of uncertain nosological validity. The category is designed to include a group of children with severe mental retardation (IQ below 35) who show major problems in hyperactivity and in attention, as well as stereotyped behaviors. They tend not to benefit from stimulant drugs (unlike those with an IQ in the normal range) and may exhibit a severe dysphoric reaction (sometimes with psychomotor retardation) when given stimulants. In adolescence, the overactivity tends to be replaced by underactivity (a pattern that is not usual in hyperkinetic children with normal intelligence). This syndrome is also often associated with a variety of developmental delays, either specific or global. The extent to which the behavioral pattern is a function of low IQ or of organic brain damage is not known.
F84.5	<i>Asperger's syndrome</i>
	A disorder of uncertain nosological validity characterized by the same type of qualitative abnormalities of reciprocal social interaction that typify autism, together with a restricted, stereotyped, repetitive repertoire of interests and activities. It differs from autism primarily in the fact that there is no general delay or retardation in language or in cognitive development. This disorder is often associated with marked clumsiness. There is a strong tendency for the abnormalities to persist into adolescence and adult life. Psychotic episodes occasionally occur in early adult life.
	Autistic psychopathy
	Schizoid disorder of childhood
F84.8	<i>Other pervasive developmental disorders</i>
F84.9	Pervasive developmental disorder, unspecified

Duane, Alexander

Fred R. Volkmar

Child Study Center, Irving B. Harris Professor of Child Psychiatry, Pediatrics and Psychology, Yale Child Study Center, School of Medicine, Yale University, New Haven, CT, USA

Name and Degrees

Duane F. Alexander

B.S. Pennsylvania State University 1962

M.D. Johns Hopkins University, M.1966

Internship, Residency, and Fellowship in Pediatrics Johns Hopkins University

Major Appointments (Institution, Location, Dates)

National Institute of Child Health and Human Development Washington, D.C., Director 1986–2009

Major Honors and Awards

His numerous awards included the USPHS Commendation Medal, a Meritorious Service Medal of Special Recognition, and the Surgeon General's Exemplary Service Medal. He also received the Arnold J. Capute Award from the American Academy of Pediatrics and the Dr. Nathan Davis Award for Outstanding Government Service from the American Medical Association. At the time of his retirement, he had achieved the rank of Assistant Surgeon General (Rear Admiral).

Landmark Clinical, Scientific, and Professional Contributions

During his directorship of NICHD, he undertook a number of initiatives including in the areas of amniocentesis, early screening for developmental disability, and sudden infant death. His work in

helping prevent the maternal-to-child transmission of HIV in the United States is particularly important as well as his work on syndromes like Fragile X and Rett. In the area of autism research, Dr. Alexander had a critically important role in the establishment of the Collaborative Programs of Excellence in Autism. He worked with program officer Dr. Marie Bristol Power in developing this highly innovative project to support research at ten institutions around the country. This work was central in facilitating the growth of multidisciplinary work in autism, and Dr. Alexander's support of work on Autism came at a time when federal supports was limited. His championship of the highest quality work in autism came at a time when autism appeared to be a disorder "without an agency." His visionary approach and leadership catapulted the science of autism forward, and many of the advances emerging today stem from the unique experiences afforded by the CPEA to young scholars, whose collaborative work with senior investigators and other junior investigators laid the foundation for innovations and breakthroughs that continue to benefit many individuals with autism spectrum disorder. The funding of the network ended in 2007 when the NIH consolidated its funding for autism research into new programs.

Short Biography

A tireless advocate for children with disabilities and retired leader of the National Institute of Child Health and Human Development, Dr. Alexander passed away on February 20, 2020. A native of Annapolis, MD, he graduated from Pennsylvania State University and received his medical education from Johns Hopkins University School of Medicine where he also completed his internship and residency in pediatrics. He joined NICHD in 1968 and also was a fellow in pediatrics focusing on developmental disabilities at the John F. Kennedy Institute for the Habilitation of the Mentally and Physically Handicapped Child (today known as the Kennedy Krieger Institute).

He served as the Director of NICHD from 1986 until his retirement. He served as medical officer in the Office of the Assistant Secretary for Health

in what is now the Department of Health and Human Services (HHS). During that time, he was also a physician on the staff of the National Commission for the Protection of Human Subjects of Biomedical and Behavioral Research, whose recommendations form the basis of current HHS regulations that protect human subjects in research. He served as NICHD Deputy Director starting in 1978 and was acting director for a time before becoming NICHD Director in 1986. For more than a decade, he also served as the United States' observer on the Steering Committee on Bioethics for the Council of Europe.

Dr. Alexander became an assistant to the scientific director in 1971 and was also an Assistant Secretary for Health in what is now the Department of Health and Human Services. He was active in the area of protection of human subjects and became NICHD Deputy Director starting in 1978; he became the Director in 1986 and served in this role until 2009.

Due Process

Kristin Ruedel

Department of Special Education, University of Maryland Washington State University, Richland, WA, USA

Definition

The due process hearing and other procedural safeguards provide a system of checks and balances for schools and parents. The due process principle essentially aims to ensure that schools and parents are held accountable to each other for carrying out the student's rights as outlined in the Individuals with Disabilities Education Act (IDEA). A due process hearing may be requested by the parents or the school district if they are in disagreement about any of the following: identification, evaluation, placement, the IEP document, or the provision of a free and appropriate education (FAPE) to a child.

A due process complaint must be filed in written form and must contain the following specific information: the name of the child, the address of the residence of the child, the name of the school the child is attending, a description of the nature of the child's problem related to the proposed action, a statement of how requirements of part B of IDEA or its implementing regulations have been violated, the facts upon which the statement is based, and a proposed resolution of the problem. A copy of the due process complaint must be provided to the other party, and a copy must be forwarded to the state educational agency.

A due process hearing is like a mini-trial before an impartial, third-party, hearing officer and is similar to a regular courtroom trial. The hearing officer is responsible for listening to both sides of the dispute, examining all related issues, and settling the dispute. Parents have the right to be accompanied or advised by counsel, present evidence, cross-examine witnesses, and see the evidence presented by the school district 5 days

prior to the hearing. Parents also have the right to have the child present at the due process hearing, but it is not required. Only a small number of disagreements between parents and schools result in parents filing a due process petition. Even fewer cases actually proceed to a hearing. If either the parent or the school district is dissatisfied with the outcome of the hearing, they have the right to appeal the decision to state or federal courts.

The school district is responsible for scheduling a resolution or mediation meeting with the parents within 15 days of receiving a due process complaint. Under the IDEA provisions, the school district and parents have 30 days from the date that the due process complaint was filed to reach an agreement through the process of resolution or mediation. If the parties are not able to reach an agreement by the end of these 30 days, then a due process hearing must be held and final decision issued within the next 45 calendar days. In some cases, the parents or the school district may choose to expedite the due process hearing. If this is the case, then a due process hearing must be conducted within 20 school days after receiving the due process complaint and the decision must be issued within 10 school days after the hearing.

Historical Background

The due process provision has been a part of IDEA since its inception. Under the procedural safeguards provision in IDEA, parents and school districts have the right to a due process hearing and the rights that go along with those hearings. Procedural safeguards are the protections in IDEA that ensure that students with disabilities and their parents or guardians are meaningfully involved in all decisions related to the student's special education and that they have the right to seek a review of any decisions they think are appropriate. The procedural safeguards are grounded in the 5th and the 14th Amendments of the US Constitution, which guarantee that no person shall be deprived of

life, liberty, or property without due process of the law.

Current Knowledge

The recent 2004 amendments to IDEA emphasized the importance for parents and school districts to resolve disputes collaboratively and quickly. IDEA encourages parents and schools to utilize alternative methods for resolving their dispute prior to proceeding to a due process hearing. First, the IDEA recommends resolution and then mediation as methods for resolving agreements prior to proceeding to a due process hearing.

Under the current 2004 amendments to IDEA, parents and school districts have up to 2 years to file a due process complaint. Exceptions to the 2-year timeline may apply if the parent was prevented from filing the due process complaint due to misrepresentations by the school district or if the school district withheld information that was required to be provided to the parent under the statutes and regulations of IDEA. States do have the right to change the 2-year timeline as they desire. If a state decides to shorten or lengthen the timeline, this information must be included and explained in the procedural safeguards notice that the school district is required to provide to parents so that parents are fully informed of the timeline limitations within their individual state.

Key changes implemented under the amendments to the IDEA 2004 statutes and regulations include the following:

1. *Notification:* Parents and/or school districts filing a due process complaint must provide notice to the other party as well as the state educational agency. Further, school districts are required to provide parents with notice of their procedural safeguards and information about free or low-cost legal services in the area.
2. *Specific timelines for responding to a due process complaint:* If the school district has not already provided parents with written notice regarding their actions relating to the issue addressed in the due process complaint, the

school district must now respond within 10 days of receiving the due process complaint. The response must include an explanation of why the school district has proposed or refused to take the action addressed in the complaint. The response must include a description of (a) options that the IEP team considered and why those reasons were rejected; (b) the evaluation procedure, assessments administered, and reports reviewed by the IEP team; and (c) any additional factors related to the case.

3. *Specific timelines for conducting a resolution meeting:* The school district must convene a meeting with the parent within 15 days of receiving the due process complaint. The purpose of the meeting is to resolve the dispute if possible. This meeting may be waived if the parents and school district agree in writing to waive the meeting or if the parent and school district agree to use the mediation process as opposed to a resolution meeting. If the school district fails to respond to the due process complaint or fails to participate in a resolution meeting within 15 days of receipt of the complaint, the parent may contact the hearing officer to begin the due process hearing timeline.
4. *Request by the school district to dismiss the case:* If a school district has made reasonable, documented efforts to schedule a resolution meeting with the parent and the parent has been nonresponsive, the school district may request that the hearing officer dismiss the case after 30 days.
5. *Requirements for resolution meeting agreements:* In the case that the parents and school district are able to resolve the dispute during a resolution meeting, both parties are required to sign a legally binding document stating the agreement. This document may be voided by either party within 3 business days but otherwise is enforceable in any state or district court.
6. *Timelines for conducting the hearing and issuing a final decision:* After the 30-day resolution period, the due process hearing and final decision must be conducted within 45 days. By the end of the 45-day period, not only must the hearing be conducted but also a final decision issued by the hearing officer, and a copy of the

decision must be mailed to the parents and the school district. The IDEA amendments also allow states the opportunity to review the decision of the hearing officer. The state has 30 days to review the decision and provide a written copy of their review decision to the parents and school district.

7. *Hearing officer requirements and decisions:* The hearing officer cannot be an employee of the state or school district where the child attends school. The hearing officer must not only have knowledge of the provisions of the IDEA as well as federal and state regulations related to the IDEA statutes but also the ability to conduct hearings and document decisions according to standard legal practice. The decision of the hearing officer in the due process hearing must be based on substantive grounds. A hearing officer may determine that a child did not receive a free and appropriate education (FAPE) if the procedural inadequacies of the school district obstructed the parent's opportunity to participate in the identification, evaluation, and IEP development process; interfered with the child's right to a FAPE; or caused a deprivation of educational benefit.

Definition

Duloxetine is a selective serotonin and norepinephrine reuptake inhibitor. Serotonin is a mood-regulating neurotransmitter, while norepinephrine is mainly involved in attentiveness. By inhibiting the reuptake of these two neurotransmitters, duloxetine increases their levels and action durations in the neuronal synapse. While both serotonin and norepinephrine have been implicated in autism to various degrees, there is no substantial evidence of duloxetine's effectiveness in treating ASD. Duloxetine is approved for use as an antidepressant and anxiolytic. It is also used in the treatment of fibromyalgia and diabetes-associated

nerve damage. Side-effect profiles are highly varied including nausea, vomiting, heartburn, diarrhea, and many others but with an unknown incidence.

³Endicott College, Beverly, MA, USA

Skinner (1957) proposed a system of classifying verbal behavior, by function and form, resulting in discrete units of analysis termed *verbal operants*. The taxonomy is based on the forms of the antecedent controlling stimuli and response products and the specific consequences provided for each operant. Skinner's original categorization included the following operants: *echoic*, *mand*, *tact*, and *intraverbal*. However, these categories of behavior do not encompass all forms and functions of communication and language. Two additional categories have since been proposed: *codic* and *duplic* (Michael 1982).

The form of a verbal operant is said to have *point-to-point correspondence* when the individual components (e.g., letters, syllables) of the antecedent stimulus and response product forms match. And, when the sense mode of the stimulus and response is the same (e.g., auditory stimulus and vocal response), they exhibit *formal similarity*. The function of each verbal operant is determined by controlling consequences or motivating operations (*mand* only). Controlling consequences are changes in stimulus conditions that follow the occurrence of verbal operants (e.g., praise), whereas motivating operations are environmental variables that alter the effectiveness of some stimulus as a reinforcer and alter the frequency of behavior that has been reinforced by that stimulus (e.g., hunger).

A *duplic* is a verbal operant in which the antecedent stimulus and response product forms exhibit point-to-point correspondence and formal similarity, and that is reinforced by generalized conditioned reinforcement from a listener (usually a parent/guardian or teacher). Common examples of *duplic*s include saying words that one hears spoken (echoic), writing words that one sees written (copying a text), or signing a word that one sees signed by another person (mimetic). *Duplic*s are learned through both direct and incidental teaching strategies and are reinforced by the learner's verbal community with praise or some form of educational reinforcement.

Dysarthria

Allison Bean Ellawadi
Speech and Hearing Science, The Ohio State
University, Columbus, OH, USA

Definition

Dysarthria is a motor speech disorder caused by generalized weakness to the oral musculature that occurs as a result of damage to the central and/or peripheral nervous system (Duffy 1995; Freed 2000; Vinson 2007; Zemlin 1998). This damage may occur as a result of stroke, head injury, cerebral palsy, muscular dystrophy, or other brain injury (American Speech-Language-Hearing Association n.d.; Freed 2000). As a consequence of oral musculature weakness, the speech of individuals with dysarthria is slow and labored, and their articulation is imprecise (Freed 2000; Zemlin 1998). Other areas of speech may also be affected including respiration, voicing, and prosody (Duffy 1995).

Dyscalculia

Diana B. Newman

Communication Disorders Department, Southern Connecticut State University, New Haven, CT, USA

Synonyms

[Developmental dyscalculia](#); [Mathematics disability](#)

Definition

Dyscalculia is a learning disability characterized by an inability to acquire the mathematical skills that would be expected for a given chronological age, cognitive ability, and educational level. Mathematics skills are typically broken down into mathematics calculation (i.e., computation) and mathematics reasoning (i.e., problem solving). Given the cumulative nature of mathematics, initial difficulty in learning and becoming fluent in basic numerical concepts impedes the later development of more complex arithmetic concepts (Butterworth 2008). For example, proficiency with whole numbers and fractions (including decimals, percent, and negative

fractions) as well as measurement and geometry has been identified as being foundational for later academic success (National Mathematics Advisory Panel 2008).

Specific characteristics of dyscalculia vary among individuals but commonly include one or more of the following: poor automatic recall of basic facts, such as multiplication tables; poor knowledge of or poor fluency in procedures for multidigit calculation, such as addition with regrouping; visuospatial weaknesses that result in place errors in written calculations and in difficulty with geometry; language deficits in areas requiring higher order thinking, thus interfering with carrying out word problems; and insufficient attention, impairing short-term memory necessary for mental arithmetic (e.g., Rapin 2010). Furthermore, those with dyscalculia not only struggle with mathematics in school but even have difficulty with numbers in everyday tasks, such as telling time and remembering phone numbers (Butterworth 2008). However, some individuals with dyscalculia often perform without difficulty in other academic areas, although there are individuals who struggle with reading and spelling, as well as mathematics.

Possible causes of dyscalculia are numerous; these include but are not necessarily limited to poor instruction, low intelligence, anxiety about numbers, behavioral and/or attentional problems, poor working memory, language-based learning disabilities, impaired visuospatial abilities, and motor skill deficits (e.g., Butterworth 2008; Zager and Donaldson 2010). Apart from environmental causes (e.g., poor teaching or behavioral issues), developmental dyscalculia may be brain-based, for example, associated with a familial-genetic predisposition (Shalev and Gross-Tsur 2001). Developmental dyscalculia also frequently occurs in neurologic disorders such as attention-deficit/hyperactivity disorder, developmental language disorder, and fragile X syndrome (Shalev and Gross-Tsur). Dyscalculia is also often associated with either a nonverbal learning disability, that is, performance is poor only in mathematics (but also reading and

spelling), or a comorbid condition of reading/spelling and mathematics disabilities.

Particular to autism spectrum disorder (ASD), studies have found that on mathematics assessments, approximately 25% of those students with high-functioning ASD perform at least one standard deviation below their vocabulary scores, thereby presenting with a mathematics disability (e.g., Mayes and Calhoun 2008; Zager and Donaldson 2010). The fact that nearly one-quarter of this population has a developmental dyscalculia contradicts the commonly held belief that persons with ASD have high mathematical ability levels (Williams et al. 2008).

Interventions for students with dyscalculia must address specific areas of difficulty using explicit and systematic teaching of skills. Practice and cumulative review are especially important. Often the use of visuals and/or manipulatives is of benefit in teaching and practicing mathematics concepts.

Dysgraphia

Diana B. Newman

Communication Disorders Department, Southern Connecticut State University, New Haven, CT, USA

Synonyms

[Handwriting difficulty](#)

Definition

Dysgraphia is a specific learning disability in which writing letters by hand is impaired, thereby affecting the acquisition and use of written language. Spelling difficulties may also be present in dysgraphia. Thus, an individual with dysgraphia may have problems with handwriting or spelling or both.

Importantly, handwriting (i.e., letter production) is not a simple motor act. Letter production requires visuospatial integration and motor planning for controlling the size of strokes and alignment of letters on paper, motor control and memory for hand movements involved in writing letters, and working memory for holding letters while motor acts are being planned and carried out (Berninger 2004). Similarly, spelling is not simply a visual skill. It requires both orthographic (i.e., letter-sound associations) and phonological processes (i.e., short-term memory for spoken information) (Berninger 2004).

The defining characteristic of dysgraphia is poor or slow handwriting, though additional characteristics are possible; thus, clinical subtypes of dysgraphia have been suggested: language-based or dyslexic dysgraphia, motor-executive dysgraphia, and visuospatial dysgraphia (e.g., O'Hare 1999). In dyslexic dysgraphia, writing difficulties arise from impairments in phonological processing (e.g., phonological awareness), semantics (e.g., word knowledge), and/or syntax (e.g., grammar). Writing is characterized by both poor legibility and weak spelling, though copying is typically relatively intact. Differently, a motor-executive dysgraphia is associated with a motor-planning weakness, that is, difficulty remembering the sequence of kinesthetic movements necessary to form letters correctly. As in dyslexic dysgraphia, handwriting is illegible; however, spelling is not affected and copying is impaired. Visuospatial dysgraphia results from impairment in understanding space. Characteristics are similar to motor-executive dysgraphia; however, in addition to letter formation, weaknesses also occur in margin consistency and spacing of letters. Further, along with handwriting difficulty, visuospatial dysgraphia also includes difficulty with drawing and motor-free visuospatial tasks (e.g., visually perceive [recognize] letters in the correct direction). Regardless of the clinical subtype, because those with dysgraphia focus more energy on handwriting, in order to shorten the handwriting process, they use as few words as possible in written communication.

The high prevalence of writing disabilities in individuals with autism spectrum disorders (ASD) has been well documented (e.g., Miyahara et al. 1997). Impairments in any or several domains that contribute to handwriting account for the frequency of dysgraphia in the population. These include but are not limited to problems with fine and gross motor functions that make precise manipulations of writing difficult; with proprioception, thus making it difficult to accurately develop fluid, automatic handwriting; and with vision that affects how letters are perceived and reproduced (Fuentes et al. 2009). Research has found that some children with ASD have problems forming letters, but not sizing, spacing, or aligning them (Fuentes et al. 2009).

It is important to address dysgraphia with appropriate treatment. Mechanics of writing, especially handwriting fluency, are predictive of both the fluency (rate) and quality of written compositions. Difficulties with the mechanics of writing (i.e., constructing letters and spelling) interfere with the same attentional resources necessary to generate meaningful composition (Berninger et al. 1997).

Dyslexia

Moirá Lewis

Speech-Language Pathologist, Marcus Autism Center Children's Healthcare of Atlanta, Atlanta, GA, USA

Synonyms

[Developmental reading disorder](#); [Specific reading disability](#)

Short Description or Definition

The National Institute of Neurological Disorders and Stroke defines dyslexia as “a brain-based type of learning disability that specifically impairs a person's ability to read. These individuals typically read at levels significantly lower than expected despite having normal intelligence. Although the disorder varies from person to person, common characteristics among people with dyslexia are difficulty with spelling, phonological processing (the manipulation of sounds), and/or rapid visual-verbal responding. In adults, dyslexia usually occurs after a brain injury or in the context of dementia. It can also be inherited in some families and so on, and recent studies have identified a number of genes that may predispose an individual to developing dyslexia.”

Categorization

Learning disability
Neurological disorder

Epidemiology

Dyslexia is known as a neurological disorder in that there appear to be differences in brain functioning associated with language, learning, and reading in this population. Dyslexia is typically not acquired but related to congenital factors and frequently occurs in related family members. Current genetic research suggests that a number of genes exist that may predispose a child to developing dyslexia. Dyslexia is usually detected and diagnosed in early elementary years, when affected children demonstrate difficulties with classroom demands related to alphabet learning, word recognition, reading comprehension, spelling, and writing. It is thought to affect between 5% and 10% of the population although there have been no studies to indicate an accurate percentage. In adults, symptoms associated with dyslexia can occur following a brain injury/stroke, or as a result of developing dementia.

Natural History, Prognostic Factors, and Outcomes

Although typically not diagnosed until middle elementary grades, dyslexia is frequently associated with delayed language development during the preschool period. Although the language delay often appears to resolve in primary grades, learning to read and write is often slow and laborious. Children with dyslexia demonstrate difficulties in phonological awareness during primary school years; they have trouble identifying rhymes, recognizing words that start or end with the same letter, and breaking words down into component sounds (hit = /h/ + /I/ + /t/). Although in multisensory interventions children “experience” letters and words in various tactile modalities (such as feeling sandpaper letters or making letters in finger paint), the approach with the best evidence base is prolonged, intensified exposure to phonological awareness training, letter-sound correspondence, sound analysis (what sounds are in the word *cat*?), and sound-word synthesis (What word do these sounds make s-u-n?). With intensive instruction, many children with dyslexia

learn to read and write, although both may remain slow and labored. For students with severe dyslexia, educational practice requires alternative access to curricular texts by means of material to be read to the student, or recorded for listening. Computer applications that translate text to speech are also used. With appropriate compensations, individuals with dyslexia can achieve high levels of independence and achievement. However, many suffer from poor self-esteem if compensations and support are not provided.

Clinical Expression and Pathophysiology

The symptoms of dyslexia may vary, depending on the age of the individual and the severity of their difficulties. In young children, delayed language, trouble identifying and segmenting sounds, rhyming, and letter-sound matching are often seen. Children with dyslexia are commonly thought to simply “reverse” letters in their reading and writing; however, many typical children reverse letters when learning to read and write. In fact, a person with dyslexia may show no pattern of letter reversal at all. Although children and adults with dyslexia tend to have average to above-average cognitive skills, they may demonstrate associated difficulties with reading comprehension, writing, as well as math, as these areas also require connection and understanding of letters/graphics.

Evaluation and Differential Diagnosis

Thorough measures of neuropsychological assessment exist in order to detect and treat dyslexia in children from an early age. Assessment for a child showing delayed or impaired reading acquisition may include cognitive and academic achievement testing, as well as an evaluation of the critical underlying language skills closely linked to dyslexia (phonological awareness, letter naming, fluency). Developmental history, family history of dyslexia, and early development of speech and language should also be investigated. The presence of vision, auditory,

and attention impairments are unrelated to the reading and comprehension signs of dyslexia and should be ruled out and treated as separate disorders.

There are a number of underlying skills that comprise a person’s ability to read, including phonological awareness, alphabet decoding, automatic word recognition, and short-term memory. In young children learning to read, these skills develop along a continuum and work together for successful reading acquisition. For a child suspected of dyslexia, these skills should be carefully assessed in order to detect what areas are underdeveloped and/or causing the most difficulty. As typical children acquire these skills, their reading becomes more fluent and with a quicker pace. Pacing and fluency does not tend to come as naturally for children with dyslexia and remains a chronic difficulty for many adults with dyslexia.

Symptoms associated with dyslexia can also occur in children with other language and learning disabilities; therefore, a comprehensive assessment is necessary to evaluate areas of reading, writing, comprehension, and verbal expression. Many children with reading problems also have spoken language deficits.

Treatment

Depending on the varying degrees of difficulty and the areas most impaired in an individual with dyslexia (i.e., letter/word recognition, reading fluency, comprehension), treatment methods and intensity of approach will vary. For children, strategies and supports in developing phonological skills (e.g., letter-sound recognition, sound separation, segmentation, rhyming) will ultimately assist with reading and writing deficits. For school-aged children who have acquired reading but continue to struggle, teaching strategies should address pacing, processing, and comprehension. Regardless of student age, a team of professionals should consult and collaborate to develop an educational plan with specific teaching methods and accommodations to meet the needs of the child.

School professionals and clinicians, particularly reading specialists, special educators, and speech-language pathologists, are trained to develop interventions and treat dyslexia. Multi-sensory approaches that target auditory, visual, and tactile areas associated with reading and comprehension offer thorough methods to address difficulties caused by dyslexia. A thorough assessment and teacher report can also offer information related to individual learning styles. For example, individuals who benefit from visual versus purely auditory teaching methods.

Assessment can also reveal the specific reading skills that require remediation for a child or adult, including:

- Phonemic awareness: recognition of the letter sounds in words
- Phonological awareness: understanding that words can be broken down into phonemes and those phonemes can be manipulated, such as segmenting sounds in words, blending sounds, and rhyming (sounds are distinct from meaning)
- Reading fluency: spelling, speed, accuracy, and ease
- Oral reading: proper expression and fluency
- Reading comprehension: includes vocabulary knowledge and understanding the meaning of passages

For adults, individualized tutoring can provide both structured and tailored teaching to address problem areas and monitor progress. Counseling sessions with a trained clinician familiar with dyslexia can provide a supportive arena to develop and discuss strategies for home and career settings where reading is involved. Counseling is also beneficial for individuals with dyslexia who demonstrate fear or anxiety surrounding their reading difficulties.

Dysphasia

► [Global Aphasia](#)

Dysphoria

Micaela Violette

Yale Child Study Center, New Haven, CT, USA

Definition

A negative emotional state characterized by dissatisfaction, restlessness, anxiousness, irritability, and depression. Dysphoria is a symptom of various psychiatric disorders such as major depressive disorder, dysthymia, generalized anxiety disorder, body dysmorphic disorder, bipolar disorder, and premenstrual dysphoric disorder. Dysphoria is usually experienced during states of depression, but people with bipolar disorder may also experience dysphoria during manic or

hypomanic episodes. Dysphoria is the opposite of euphoria.

Dyspraxia

Susan Latham
Department of Communication Disorders, St.
Mary's College (IN), Notre Dame, IN, USA

Synonyms

[Apraxia](#)

Definition

The term “dyspraxia” is often used to describe less severe forms of apraxia. Apraxia is the disruption in the ability to plan and execute volitional (purposeful) movements despite intact muscle strength and coordination. Involuntary movements remain intact. Importantly, apraxia is not associated with weakness, slowness, or incoordination. Apraxia is a motor disorder resulting from neurological damage. There are three types of apraxia: limb, oral, and verbal. In a limb apraxia, the volitional movements of the extremities are affected. In an oral apraxia, nonspeech

movements of the oral mechanism are affected. Verbal apraxia (or Apraxia of Speech) is a disorder in which an individual has difficulty positioning and sequencing muscles for the volitional production of speech.

Dystonia

Claudia Califano

Yale-New Haven Hospital, New Haven, CT, USA

Definition

A movement disorder characterized by involuntary movements and prolonged muscle contraction, resulting in twisting body motions, repetitive movements, or abnormal posture (Fahn et al. 1998; Geyer and Bressman 2006). These movements may involve the entire body or only an isolated area. Dystonia can be hereditary or occur sporadically without any genetic pattern; it can occur as a result of birth related or other trauma or may be associated with medications, particularly neuroleptics, or diseases. The gene responsible for at least one form of dystonia has recently been identified. Some types of dystonia respond to dopamine or can be controlled with sedative-type medications or surgery. Dystonias may be classified by the age of onset, by the part (s) of the body affected, or by the cause (primary or secondary dystonia).

Primary dystonia presents with signs only related to the dystonia and is thought to be caused by pathology in parts of the brain that are concerned with movement (basal ganglia) and the GABA (gamma-aminobutyric acid) producing neurons. This dystonia occurs without additional neurologic, laboratory, or imaging abnormalities. The precise cause of primary dystonia is unknown. In many cases, it may involve some genetic predisposition towards the disorder combined with environmental conditions.

Secondary dystonia refers to dystonia associated with a known cause or additional neurologic findings. It usually arises as the result of a specific underlying condition such as insufficient oxygen at birth and exposure to medications that block dopamine receptors (Friedman and Standaert 2001).

Treatment of dystonias is based upon the symptomatology. There are no curative therapies, although in the case of medication-induced dystonia, discontinuation of the medication may result in a resolution of some dystonic symptoms. Management of dystonia includes medications such as levodopa, anticholinergics, tetrabenazine, clonazepam, and baclofen. Botulinum toxin injections and deep brain stimulation are also recognized treatments.

Early Diagnosis

Tony Charman
Centre for Research in Autism and Education,
Department of Psychology and Human
Development, Institute of Education, University
of London, London, UK

Definition

Although autism spectrum disorders can be diagnosed at any age, the classification systems require onset prior to 3 years of age or in early childhood. The term “early diagnosis” refers to diagnosis in the second and third year of life.

Historical Background

Notwithstanding progress in understanding of the genetic and neurodevelopmental processes that lead to autism spectrum disorders (ASD), clinical diagnosis is reliant on the developmental and behavioral presentation. Until the 1990s, it was

rare for children to receive a diagnosis of autism until the age of 3 or 4 years, and sometimes considerably later (Howlin and Asgharian 1999). This was despite the fact that the DSM and ICD diagnostic systems (American Psychiatric Association [APA] 2000; World Health Organization [WHO] 1993) require that the symptoms be evident in the first 3 years of life, although in the proposed modifications in DSM-5, this requirement has been changed to “Symptoms must be present in early childhood (but may not become fully manifest until social demands exceed limited capacities).” However, nowadays many children are now first identified in the toddler and pre-school period (Charman and Baird 2002; Mandell et al. 2005; Manning et al. 2011), although others, in particular those with average or above average language and cognitive abilities, are not diagnosed until school age or older. Several factors have driven this change, including efforts to improve earlier identification with the recognition that earlier-delivered intervention may improve outcomes and prevent “secondary” neurodevelopmental disturbances (Dawson 2008; Mundy et al. 2009); the development of prospective screening instruments to identify possible cases of autism from the first few years of life (Barbaro and Dissanayake 2009); and the use of the genetic “high-risk” research design of prospectively studying younger siblings of children with a diagnosis of ASD from the first year of life (Rogers 2009; Yirmiya and Charman 2010).

Current Knowledge

One of the most significant challenges and concerns of this new era of prospectively studying children with autism spectrum disorders from the age of 2 and 3 years concerns diagnosis. Given the relatively lack of experience of applying the diagnostic criteria to children of this age, even among the relatively expert clinical teams conducting such research programs, one critical question was whether the diagnosis was possible, accurate, and stable when applied to toddlers at the age of 2 or 3? Over the past decade, a number of research teams have followed up children first seen at the age of 2 years into early, and more recently middle, childhood and provided an answer, to some extent, to this important question.

A number of studies have examined the stability and accuracy of diagnosis, both in samples of children referred for assessment at an early age and from screening studies. Over the past decade, these diagnostic outcome studies have followed cohorts of children from initial diagnostic assessments around the age of 2 years into the preschool years and in several of the more recent studies (Charman et al. 2005; Lord et al. 2006; Turner et al. 2006) into the school age years. The first series of studies (Cox et al. 1999; Lord 1995; Moore and Goodson 2003; Stone et al. 1999) all showed high stability of diagnosis in particular for “core” autism, with somewhat lower stability for broader autism spectrum disorder (ASD) and pervasive developmental disorder not otherwise specified (PDD-NOS). The movement across the ASD/PDD-NOS diagnostic category boundary was somewhat different in the different studies, with Stone et al. (1999) finding that 4 out of 12 children who met broader ASD criteria at the initial assessment did not meet criteria for an autism spectrum disorder at follow-up, whereas Cox et al. (1999) found that 7 from 31 children who did not receive an autism spectrum diagnosis at the initial assessment met criteria for broader ASD at follow-up. Several of the early studies (Cox et al. 1999; Lord 1995; Stone et al. 1999) concluded that for 2-year-olds, expert clinical judgment is more reliable than the standard diagnostic instruments. Several studies also found that

behaviors from the third symptom cluster that defines autism – restricted and repetitive behaviors and activities – were less evident at 2 years of age than at 3–5 years of age (Cox et al. 1999; Moore and Goodson 2003; Stone et al. 1999).

The more recent studies differ in a number of features, most notably in that some have considerably larger sample sizes ($N = 172$, Lord et al. 2006; $N = 89$, Chawarska et al. 2009; $N = 77$, Kleinman et al. 2008) and that the follow-up periods extend to age 7 years in the Charman et al. (2005) study and to age 9 years in the Lord et al. (2006) and Turner et al. (2006) studies. Broadly, the lessons are the same – that the diagnosis of autism is highly stable in these samples but that of broader ASD is less so see Rondeau et al. (2011); for a review). Lord et al. (2006) found that age 2 scores on measures of repetitive and restricted behaviors and activities predicted an autism diagnosis at age 9 years. In some of these more recent studies, there was greater movement from having an ASD diagnosis at age 2 years to a non-spectrum diagnosis at age 4 (Kleinman et al. 2008; Turner and Stone 2007). While the authors report the factors associated with these “good outcomes” – principally higher IQ and better language competency – it is important to remain cautious regarding predictors of poorer or better outcomes in children diagnosed at such a young age.

Future Directions

For clinicians, the lesson is to accept that autism is a developmental disorder and at a very young age, there may be less certainty regarding the pattern of behavior that a child is showing and the likelihood of them continuing to meet diagnostic criteria into the future. Charman and Baird (2002) discuss the importance of understanding the diagnostic process as an iterative process to be worked out between clinician teams and parents over time and that concepts such as a “working diagnosis” can be helpful. An important aspect of early diagnostic consultation is an open and straightforward approach to the negotiation of the diagnostic view

with parents over time. At the same time, clinical teams need to be aware of the need to provide sufficient certainty regarding the child's condition that they are not refused services following assessment.

Clinical work is often concerned with those children who do not clearly meet full criteria for childhood autism but who have apparently milder social problems or where there are mixed developmental difficulties. Clinical experience also suggests that some children who show definite features of autism earlier make remarkable developmental progress. Therefore, caution must be used, especially under 3 years, for those children with features of the broader autistic spectrum who may attract a PDD diagnosis. Experienced clinicians report that parents understand the difficulties of certainty in developmental assessment. Most appreciate honesty on professionals' part about the difficulty of reaching a precise prognosis on a very young child and can understand a frank discussion about the possible outcomes if accompanied by appropriate advice and help for intervention. Understanding why one's child behaves as he or she does is half way to doing something about it.

One other important clinical reminder is that while the trajectory of early emerging impairments in social and communication development accompanied by rigid and repetitive behaviors and interests characterizes many children on the autism spectrum, there is a subgroup of particularly verbal and able children who go on to receive a diagnosis of autism (sometimes called "high functioning autism") or Asperger syndrome who may not receive a diagnosis in the preschool years. There is also another group who might meet diagnostic criteria for an autism spectrum disorder who do not receive an explicit diagnosis – those individuals with moderate to severe intellectual disability or those with an already identified preexisting associated medical condition. In a recent epidemiological study, Baird et al. (2006) found that for cases meeting research diagnostic criteria for an ASD following in-depth assessment, low IQ predicted those who had not received a clinical diagnosis by local clinical services by age 10 years.

One final caveat is that the studies summarized have largely come from expert research clinical centers specifically studying young cohorts of children. In community settings in many countries, there is evidence including from recent studies that for many children and their families, a diagnosis is not confirmed until children are well into the school age years and this has implications for the training of community practitioners (Wiggins et al. 2006).

Early Intensive Behavioral Intervention (EIBI)

Susan Hepburn

Department of Psychiatry and Pediatrics, JFK Partners, University of Colorado at Denver, Aurora, CO, USA

Colorado State University, Department of Human Development and Family Services, Fort Collins, CO, USA

Definition

Early intensive behavioral intervention (EIBI) is a treatment approach that is based upon the principles of applied behavior analysis (ABA) and the research of Ivar Lovaas and colleagues at the UCLA Young Autism Project. The EIBI approach has been extensively studied and actively debated in the scientific literature, popular media, and policy arena.

Historical Background

Developed by Lovaas and colleagues across several years of research and development at the University of California–Los Angeles, the EIBI approach has been extensively studied and actively debated in the scientific literature, popular media, and policy arena. Influenced by theories of learning and motivation, practitioners of EIBI refer to it as “the science of teaching.”

Rationale or Underlying Theory

Applied behavior analysis is the overarching philosophy underlying EIBI. Integrating principles from learning theory, operant conditioning, behavioral economics, and motivational theory, proponents of EIBI value the power of changing aspects of the teaching context in order to promote child gains. By providing systematic, direct instruction in an intensive manner (i.e., 30–40 h per week, 1:1 with an adult), proponents of EIBI suggest that young children with autism can improve significantly.

Treatment Participants

Early intensive behavioral intervention (EIBI) is a treatment approach that is thought to benefit children with autism who are younger than 5 years of age. Developers of the intervention emphasize the importance of beginning when a child is as young as possible, hopefully younger than 3 1/2 years.

There is some evidence that children who are more intellectually competent respond best to EIBI.

Treatment Procedures

Based upon the principles of applied behavior analysis (ABA), an EIBI program usually includes these characteristics: (1) active engagement of the child for 40+ h per week in (2) playful intervention, (3) delivered primarily in direct, 1:1 child-adult instruction (4) with specific individual goals, (5) carefully operationalized instructional objectives and procedures, and a (6) data collection system to promote objective observation and (7) analysis of a child's behavioral responses to different aspects of instruction. (8) Teaching strategies are then dynamically revised based upon this analysis, (9) implemented consistently across providers, and (10) evaluated again for effectiveness by monitoring the child's trajectory of skill acquisition. The built-in evaluation system enables families and providers to make dynamic decisions about how and where to modify

approaches, as the child progresses and/or faces new challenges. Young children participating in this treatment usually spend 6–8 h per day in treatment sessions, with breaks every 2–3 h. Often, the sessions happen in the child's home.

Efficacy Information

There is a debate between the proponents and critics of the effectiveness research documenting EIBI, as summarized below (see References and Reading).

Proponents' View

1. Meta-analytic methods (i.e., statistically analyzing all available data across several different studies) and comprehensive scientific reviews support the effectiveness of EIBI for some, but not all, children (Eldevik et al. 2011; Howlin et al. 2009; Matson and Smith 2007; Peters-Scheffer et al. 2011; Reichow and Wolery 2009).
2. Many of the teaching strategies used in EIBI are evidence-based (National Standards Project 2010), including discrete trial training, frequent reinforcement, and ongoing assessment of child behavior.

Critics' Views of EIBI

1. It can be difficult to implement an intensive treatment model for many families, both with regard to time, family stress, and financial resources (Gresham and MacMillan 1998; Schopler et al. 1989).
2. Some of the studies that are in the literature do not demonstrate a lot of improvement, and it is difficult to know which children will respond best to this particular model of intervention.
3. Some researchers are critical of features of the studies which are frequently cited as demonstrative of effectiveness of EIBI (i.e., Lovaas 1987; McEachin et al. 1993; Smith et al. 2000). For example, some early outcome studies reported a return to normal functioning for a substantial number of children (Lovaas 1987), which has been refuted by other scientists

(Shea 2004). Some researchers have expressed caution in interpreting the findings for effectiveness of EIBI, in part due to the ways the outcomes were measured and how decisions about group membership were made, issues of sample size, variability of characteristics of children across studies, lack of intervention fidelity across sites, and some inconsistent findings in studies conducted at replication sites (Bassett et al. 2000; Gresham and MacMillan 1997a, b; Howlin et al. 2009; Myers et al. 2007; Spreckley and Boyd 2008).

4. Developmentally oriented practitioners suggest that the curricula are not sequenced/implemented in a way that is consistent with principles of effective early childhood education.
5. Prioritizing 1:1 direct instruction with the child usually means foregoing instruction in group settings (i.e., preschool), and the child may lack opportunities to learn social and communication skills in real-life settings with other children.
6. Some children become passive learners, cooperative in instructional sessions but not able to spontaneously practice the targeted skill in natural settings.
7. Parent and family involvement is not necessarily a part of the intervention program.

Outcome Measurement

1. Many young children make significant gains in overall developmental functioning with this approach, with improvements in IQ scores ranging from 15 to 25 points after 2 years of intensive intervention during early childhood (see Fenske et al. 1985; Lovaas 1987; McEachin et al. 1993; Sheinkopf and Siegel 1998; Smith et al. 2000). There is some evidence that children who are more intellectually competent respond best to EIBI.
2. Several studies examined school placement and report that children receiving EIBI were likely to be fully included in general education classrooms at first grade (Sallows and Graupner 2005).

Qualifications of Treatment Providers

EIBI is most effective when delivered and supervised by a team of well-trained professionals (Bibby et al. 2001; Smith et al. 2000). EIBI teams tend to be multidisciplinary, with team members who are certified behavior analysts, speech therapists, educators, occupational therapists, and paraprofessionals.

Early Intervention

Moira Lewis

Speech-Language Pathologist, Marcus Autism Center Children's Healthcare of Atlanta, Atlanta, GA, USA

Synonyms

[Birth-to-three](#); [EI](#)

Definition

Early intervention (EI) refers to publicly funded programs available to infants and toddlers with disabilities and their families, through the Individuals with Disabilities Education Act (IDEA), first authorized by congress in 1986. EI programs offer specialized health, educational, and therapeutic services designed to meet the needs of children, from birth up until age 3, who have a developmental delay or disability, and their families. EI programs often have various names among different states. For example, the statewide EI program in Connecticut is often referred to by parents and professionals as "Birth-to-three," while those in Georgia use the program name "Babies Can't Wait." EI programs receive both federal and state funding, in order to offer services to families free of charge.

To be eligible for services, children must be less than 3 years of age and have a confirmed

disability or established developmental delay, as defined by their state of residence, in one or more of the following areas of development: cognitive, communication, social-emotional, motor skills, and/or adaptive skills.

Following developmental evaluation to determine eligibility, services are typically delivered to children in their home, or within community and center-based programs, or other natural environments. EI service providers include special educators, social workers, speech therapists, physical therapists, occupational therapists, nurses, psychologists, and nutrition specialists.

EI programming may also be provided to children who are considered to be at risk of developing substantial delays if services are not provided.

The following are considered overarching goals of EI: to reduce the likelihood of delays among at-risk children, support improved outcomes and independence among children with developmental disabilities throughout the lifespan, empower and educate families, and to provide intervention to children, regardless of race, ethnicity, or income.

Early Language Milestone Scale

Moirá Lewis

Speech-Language Pathologist, Marcus Autism Center Children's Healthcare of Atlanta, Atlanta, GA, USA

Synonyms

[Early language milestone scale-2](#); [ELM scale-2](#)

Description

The Early Language Milestone Scale-2 (ELM Scale-2) was developed for use in pediatric clinical settings as a brief screening of the language abilities of children under the age of 3 years (Coplan 1993). Responses are obtained from a combination of parental/caregiver report, examiner observation, and direct testing. This assessment has three sections: auditory expressive, auditory receptive, and visual. It also provides screening for speech intelligibility (how understandable the child's speech is) at 3–4 years of age. The instrument is composed of 43 items and takes approximately 10 min to administer. The ELM Scale-2 is available in English only.

Historical Background

The ELM Scale-2 was published in 1993, authored by James Coplan, M.D.

Psychometric Data

The measure has a relatively small normed sample of under 200 children under 3 years of age with no breakdown by age within the sample. Eighty percent of the sample is classified as white and 20% is classified as "nonwhite." Eighty percent of the sample is classified as middle-class socioeconomic background and 20% from "lower" socioeconomic background groups. The manual reports higher

inter-rater reliability, but lower test-retest specificity. Concurrent validity data reported supports the use of the ELMS-2 as a screening instrument, to be completed prior to a more thorough communication assessment, if warranted. Although specificity is high, suggesting the measure is valid for identifying 24-month-old children who have normal language development, sensitivity is lower, so that it may be less useful for identifying children with the possibility of language delay.

Clinical Uses

This test is quick and easy to administer with little training. Aside from standardized, comprehensive language assessments administered by trained speech-language pathologist, the ELM Scale-2 can be administered by other medical and healthcare practitioners in pediatric clinical settings and early intervention settings.

The ELM Scale-2 contains scoring options, as it may be administered using a "pass/fail" or a point scoring method. The pass/fail method yields a global pass or fail rating for the test as a whole, whereas the point scoring yields percentile values, standard scores, and age equivalents for each area of language function mentioned above. Its properties suggest it is a viable screening measure; however, due to the small and limited normative sample, standard scores provided for the ELM Scale-2 must be used with caution.

Early Social-Communication Scales (ESCS)

Amanda Steiner
Yale Child Study Center, New Haven, CT, USA

Synonyms

[ESCS](#)

Description

The Early Social Communication Scales is a structured assessment designed to provide measures of individual differences in nonverbal communication skills in children with mental ages between 8 and 30 months of age. The administration requires 15–25 min involving the presentation of approximately 17 tasks which provide opportunities for social communication. Tasks include the presentation of object spectacle toys (e.g., a wind-up toy), turn-taking tasks (e.g., ball play), social interaction (e.g., tickling), gaze following tasks, and opportunities to respond to an invitation to play. The child is typically seated across the table from the examiner, and may be either seated in a chair or seated in their parent’s lap.

The session is videotaped and from the recordings, observers classify children’s behaviors into the following mutually exclusive categories of early social-communication: joint attention behaviors (use of nonverbal behaviors to share experiences), behavioral requests (use of nonverbal behavior to obtain objects or events), and social interaction behaviors (ability to engage in playful turn-taking behavior). These behaviors are also classified based on whether or not they are child-initiated bids or child responses to the examiner.

Historical Background

The ESCS was first developed in 1982 and from a Piagetian stage-based understanding of early development, emphasizing the complexity of a child’s social communicative skills within the context of a child’s goals with a behavior (either communicative or interpersonal). In the previous version, a set of 25 semi-structured situations were utilized to elicit social communication, with approximately 110 possible occurrences of child behavior rated in terms of its complexity, goal, and degree of initiation. The current abridged version of the ESCS was designed to be utilized as a more practical research and clinical tool.

Psychometric Data

Several research studies have been conducted exploring the performance of typically developing children and children with developmental disabilities on the ESCS as well as the reliability of the instrument. In addition, preliminary normative information is available within the ESCS manual (Mundy et al. 2003). In typical populations, performance in responding to joint attention on the ESCS between 14 and 17 months was a significant predictor of subsequent receptive language development (Mundy and Gomes 1998). Research has been conducted on the ESCS across several clinical populations, including children with Down syndrome (Mundy et al. 1995, 1988) and also infants at risk (Sheinkopf et al. 2004). In terms of ASD, research suggests that children with ASD tended to demonstrate the greatest deficits in joint attention behaviors on the ESCS, although difficulties were noted across all areas of nonverbal communication for children on the spectrum (Mundy et al. 1994). Moreover, children with ASD displayed greater deficits in gestural joint attention skills, and these skills significantly predicted language development in children with ASD (Mundy et al. 1990).

Clinical Uses

The ESCS is largely utilized as a research tool (as it requires detailed offline scoring); however, it can also be used as a clinical tool by speech-language pathologists, early childhood specialists, and psychologists, as well as other professionals trained to administer the assessment in the context of a diagnostic or developmental evaluation.

Early Start Denver Model

Sally J. Rogers
Department of Psychiatry and Behavioral Sciences, UC Davis M.I.N.D. Institute, Sacramento, CA, USA

Definition

The Early Start Denver Model (ESDM) is a comprehensive early intervention for toddlers with autism ages 12–48 months. The model resulted

from the collaboration of Sally Rogers and Geraldine Dawson and their colleagues at the University of Washington Autism Center, with Rogers' colleagues, especially Laurie Vismara, at the University of California, Davis, and at JFK Partners, University of Colorado Health Sciences Center. The approach is manualized and described in detail by Rogers and Dawson (2010b).

The ESDM and the Denver Model (DM) that preceded it were developed to target the core deficits seen in toddlers and preschoolers with autism: social orientation, attention, affect sharing and attunement, imitation, joint attention, language development, and functional and symbolic play. The ESDM has an interactive communication- and relationship-based framework that fosters active experiential learning by supporting child spontaneity and initiative. It has a developmental curriculum which incorporates teaching techniques that have received empirical support for improving skill acquisition.

The ESDM is based on a fusion of the Denver Model, an affective and developmentally-based intervention for children (ages 2–5) with autism (Rogers 2000); the nature of the teaching interactions and the curricular priorities are influenced by Stern's model of infant interpersonal development (Stern 1985) and pivotal response training (PRT), developed by Laura Schreibman and Robert and Lynn Koegel (Koegel et al. 1989). PRT involves a naturalistic application of applied behavior analysis (ABA) to develop language and social skills.

The main differences between ESDM and DM involve (1) focus on toddlers ages 12–48 months in the ESDM; (2) fusion of practices and principles of PRT with those of the DM; (3) added concept and explicit terminology from applied behavior analysis; (4) more rigorous and defined measurement practices; and (5) a well-defined curriculum appropriate for children 12–48 months of age.

The ESDM and DM have been tested in classroom applications, in one-on-one delivery, in intensive delivery of 15–20 h a week, and via parent delivery. The approach is flexible and designed to be used (1) at home, embedded within typical play and caretaking activities, and in child

care and preschool settings; (2) in 1:1 treatment sessions including parent coaching provided by credentialed providers; and (3) in group programs that can provide individual support to a child.

Historical Background

Development of the Denver Model (DM) began at the University of Colorado Health Sciences Center in 1981, in response to demonstration preschool funding from the US Department of Education. The DM had a developmental and pragmatic approach to language acquisition and emphasis on learning through play and through positive, lively relationships. An interdisciplinary strategy, including a strong role of occupational therapy, positive behavior supports, and a central role of parents, has persisted. The curriculum tool was begun during this period and enhanced and extended for toddlers in the ESDM.

The DM expanded into an approach suitable for use as a 1:1 home-based program during the 1990s. Replications in publically funded sites demonstrated that the model could be implemented in community settings and that child development significantly accelerated with its use.

Significant enhancements of the model occurred in the past 10 years, including more rigorous definitions of delivery and measurement and data collection procedures when the University of Washington tested the approach in a randomized controlled trial with a focus on toddlers (Dawson et al. 2010).

Rationale or Underlying Theory

Three theoretical models provide the foundations for the ESDM curriculum and teaching practices. These include Rogers and Pennington's model of interpersonal development in autism (Rogers and Pennington 1991), Dawson and colleagues' model of autism as a disorder of social motivation (Dawson et al. 2004), and the approach to learning defined by PRT (Schreibman and Pierce 1993).

Rogers and Pennington (1991) hypothesized a developmental model of autism that began with biologically-based deficits in imitation abilities and related impairments in emotional sharing and nonverbal communication in the first year of life. The authors were influenced by Daniel Stern's 1985 model of interpersonal development in infancy. This model presents a theory concerning autism-specific impairments in three developmentally critical behaviors – imitation, emotion sharing, and joint attention. A main focus of the ESDM is to address these critical behaviors within affectively rich relationships with responsive, sensitive others.

The ESDM has been influenced by research on another core feature of autism: impaired social motivation. Dawson and colleagues (Dawson et al. 2004, 2005) have contributed to identifying this characteristic in infants who will develop autism, and they hypothesize that the biology of autism involves a deficiency in social motivation due to the infant's lack of sensitivity to social reward. This lack of sensitivity results in a failure to have a normal preference and active attention to social information, including others' faces, voices, gestures, and speech. This failure, combined with impairments in imitation, emotional sharing, and joint attention, is an obstacle to the child's development of socio-emotional and communicative skills. As a result, the child with autism becomes increasingly removed from the social world and all the learning experiences that exist inside that world. The child falls farther behind because he or she lacks the skills needed to access the social learning environment. Dawson and colleagues have suggested that this lack of engagement not only alters the course of behavioral development but also affects the way neural systems, underlying the perception and representation of social and linguistic information, are developed and organized (Dawson 2008). Several of the strategies utilized in the ESDM are designed to increase the salience of social rewards and enhance the child's attention and motivation for social interaction.

PRT involves a naturalistic use of applied behavior analysis to develop language and social skills. The approach is flexible and is designed to

be embedded within typical play and caretaking activities at home and in child care and preschool settings. PRT is an empirically supported practice, given its documentation of enhanced child motivation, spontaneity, and social initiation and of improved language, maintenance and response generalization, and for concomitant reductions in unwanted behaviors. Child motivation is optimized by the use of reinforcers related to the child's goals and responses and child choice, interspersing acquired tasks with acquisition tasks, therapist reinforcement of attempts to perform the desired behavior, and using activities that are highly motivating to the child. Therapists take turns with the child to share control of the interaction, to capture child attention, and to model behavior that may not be in the child's repertoire.

These three orientations have in common the view that autism impedes an infant's interpersonal experiences. In so doing, it creates barriers to social-communicative development, which lead to greater impairments due to the loss of social learning opportunities.

Goals and Objectives

Goals and Objectives

The goal of ESDM intervention is to increase child social-communicative and relational learning. The main intervention objectives are (1) to bring the child into coordinated, interactive social relations for most of his or her waking hours by supporting all caregivers and therapists to embed ESDM techniques into all daily activities; (2) to provide the child with social learning tools involving imitation, joint attention, language, and social play through teaching inside all daily activities; and (3) to embed a high frequency of specific dyadic learning opportunities in each activity of daily life and also into each intervention activity to "fill in" the learning deficits that have resulted from the past lack of social learning (Rogers 2000). These goals and objectives are accomplished with the following ESDM guiding principles:

- (a) A positive emotional exchange between children and key adults. ESDM intervention activities involve a series of play routines which facilitate the child's pleasure and social engagement and create many opportunities for shared affect and reciprocal interactions.
- (b) Joint activity routines (Ratner and Bruner 1978) are the primary vehicle for teaching, and the teaching episodes are carried out inside this joint activity frame. The play interactions are child-centered, in that children's choices and preferred activities and materials are featured. The adult shares control of the play by selecting what objects are available, what actions are modeled and reinforced, and how activities are sequenced. Joint activities involve objects and activities that are found in natural environments for children of this age. All developmental skills are taught in this way, including the development of a repertoire of sensory motor and constructive, functional, and symbolic play.
- (c) The ESDM is grounded in the science of learning and uses teaching strategies consistent with the principles of applied behavior analysis. ABA has received empirical support, altering the symptoms associated with both autism and general developmental delays (Koegel et al. 1988; Lovaas 1987). Core teaching techniques from PRT that are emphasized in the model include (1) obtaining child attention before delivering an instruction or model; (2) using a clear A-B-C format in teaching trials that are embedded in play activities (the antecedent stimulus precedes the behavior, which is followed by a consequence); (3) reinforcing target skills using intrinsic reinforcers where they exist, pairing nonsocial reinforcers with social attention, and delivering contingent consequences; (4) using shaping, chaining, prompting, fading, and error correction to develop the antecedent-behavior link and to shape a partial performance to a more accurate performance.
- (d) The language intervention approach comes from the science of communication development and recognizes that verbal language develops from nonverbal communication (Bates and Dick 2002; Bruner 1975). Both verbal language and nonverbal communication coordinate people's activities and allow partners to share mental states: intentions, desires, interests, thoughts, and feelings. In each intervention session, multiple and varied communicative opportunities are provided and many communications, both verbal and nonverbal, are elicited from the child. The range of communicative functions is developed so that a child not only requests an activity but also protests, greets familiar adults, shares attention, and comments, as well as other functions. Children's spontaneous communications exert much control over interactions and activities, thus demonstrating the power of communication and assuring its reinforcement.
- (e) The ESDM views autism as disrupting development in all domains (Goodman 1989), and it uses a multidisciplinary approach to address specific domains. Children's developmental skills are evaluated in each domain, and intervention objectives are written for all areas. Though developmental patterns in autism have been understudied, research in different domains has demonstrated that young children with autism follow fairly normal trajectories of development even in their affected areas (see Lifter et al. 1993 regarding symbolic play; Tager-Flusberg et al. 1990 regarding language development; and Ungerer and Sigman 1987 regarding early sensory motor development). The curriculum domain items were extracted from research in early child development in multiple domains: cognition, expressive and receptive language, social-emotional development, fine and gross motor development, self-care skills, play, and imitation. The curriculum was developed by a team of professionals with expertise in developmental and clinical psychology, applied behavior analysis, early childhood special education, speech and language pathology, and occupational therapy. Developmental and clinical psychologists contribute to the sequence of acquisition and the normative strategies for interaction, cognitive

development, play, and imitation. Applied behavior analysts contribute empirically derived strategies for effective teaching and use of functional assessment and analysis to develop approaches for unwanted behaviors and effective teaching practices. Early childhood special education contributes expertise on cognition and play and pre-academic development. Speech and language pathology informs the sequence of speech development, the varied functions of communication, and augmentative and alternative communication approaches. Occupational therapy informs the sequence and content of motor and self-care skills, personal independence, the use of activities to build developmental skills, and optimization of arousal and sensory responsivity to facilitate attention and engagement in learning. Developmental and behavioral pediatrics contributes knowledge of the health concerns of individual children which can interfere with children's ability to benefit from the intervention.

- (f) The ESDM team provides oversight and consultation regarding treatment design and delivery to the parent and primary therapist for each child. At this time, ESDM is primarily delivered by parents and trained therapists providing 1:1 teaching, though it can also be used in group situations, and several research studies are currently in progress concerning efficacy of group delivery. Direct delivery of the intervention is generally directed by one professional, the team leader, or primary therapist, working with parents and therapy assistants in a generalist model, with the multidisciplinary team supporting that primary provider. The generalist delivery approach is used to keep the intervention consistent across treatment sessions and as economical as possible. It also models what parents need to do: address all the child's needs. The full team is available as consultants to the primary therapist and family. When ESDM is delivered in a group preschool setting, the classroom teacher takes the generalist role. The team leader must be credentialed in his or her profession and certified as an ESDM therapist. The team leader is

responsible for a variety of tasks: working with the parents to learn ESDM at home and to assess children's strengths and needs; administering the Curriculum Checklist quarterly and writing 3-month objectives and breaking them down into teaching steps; delivering the intervention and supporting the parents to do so; training and supervising any noncredentialed person who is helping to deliver ESDM; coordinating care with other professionals; and keeping and analyzing daily data and adapting the intervention plan as needed to foster rapid child progress.

- (g) Parent learn to deliver ESDM at home from their team leader, since the embedding of ESDM techniques throughout daily care and play routines is fundamental to the model and necessary for optimal progress. A manual for parents is published by Rogers, Dawson, and Vismara, *An Early Start for Your Child with Autism: Using Everyday Activities to Help Kids Connect, Communicate, and Learn* (2012, Guilford Press).

Treatment Participants

The approach is developed for young children with autism, ages 12–48 months, and developmental quotients over 35 and has been demonstrated to be effective for children with a wide range of skill levels. However, it has only been tested with ambulatory children who have functional hand use and are interested in toys and other objects. It has not been tested with children who have additional diagnoses like Down syndrome or fragile X. In all trials of ESDM, parents have learned to use the methods at home. Effectiveness when parents have not learned to use the method and are not supported on a weekly basis has not been tested.

Treatment Procedures

Each child's learning plan is defined by short-term objectives that represent what is to be learned over a 12-week period and activities carried out daily to

teach the objectives. The objectives are derived from a curriculum assessment carried out each 12 weeks using the ESDM Curriculum Checklist (Rogers and Dawson 2010b). The ESDM Curriculum Checklist covers the following domains: receptive communication, expressive communication, social interaction, imitation skills, cognitive skills, play skills, fine motor skills, gross motor skills, independence/behavior, and joint attention. Each objective is broken down into 5–6 teaching steps that lay out the build-up of the skill. A daily data sheet allows the therapist to teach skills and track progress in very small steps.

Fourteen aspects of the teaching process are quantified in the ESDM fidelity tool. A primary characteristic involves child-initiated activities in which adults embed instruction into play and other daily functional activities, since this kind of teaching has demonstrated gains in spontaneity, motivation, maintenance, and generalization. Adults provide children with choices of materials and activities to support learning of the targeted objectives and to maximize attention and motivation, while considering the child's preferences, age, developmental skills, and learning style.

Joint activity routines (Ratner and Bruner 1978) are the vehicle for teaching. A joint activity routine involves a four-part play activity between child and adult that allows for an activity to be begun, developed, elaborated, and completed. Objectives from two or more different developmental domains are addressed in each 2–5-min joint activity routine. Learning opportunities occur approximately every 10–15 seconds during these activity routines. Transitions between activities are responsive to children's need for change and are accomplished in a fashion that fosters child independence, motivation, and choice. Adult emotion is expected to be warm, positive, and playful. Adults and children interact reciprocally with objects and in communication exchanges, taking turns and sharing leader-follower roles.

Another key aspect of the teaching process involves adult language. Adults use natural language fit to the child's ongoing activity and syntactically constructed using the "one up" rule,

which specifies that the adult's language should involve sentence length that is roughly one word longer than the child's typical sentence. Adults are to narrate, comment, and label actions, objects, and emotions; to model appropriate gestures and speech; and to expand child utterances rather than to question children or tell them what to say.

Children's communication begins with gestural development and multiple pragmatic intents, with a focus on phonetic development, development of intentional vocalization, and reciprocal and meaningful vocal exchanges.

Adult-child interactions are playful and follow children's interests and motivations, addressing short-term objectives from multiple domains. Adults are expected to provide clear learning opportunities, at a rate of several per minute.

A systematic decision process (response to intervention [RTI]) is used in ESDM to "tailor the treatment," by systematically altering teaching procedures if children are not progressing rapidly. This decision tree (Rogers and Dawson 2010b) is highly articulated and allows for a "toolbox" of empirically-based teaching practices for young children with autism to be used if needed, but it prescribes *how*, *when*, and *for how long*, to alter the basic ESDM teaching processes. While the basic ESDM teaching approach favors naturalistic teaching, warm and emotionally positive relationships, varied activities, intrinsic reinforcers, and shared control, no empirically supported teaching approach is "off limits". However, the quality of relationship and communication principles of ESDM is embedded regardless of what specific teaching practices are being used.

Parents are an integral part of ESDM, and their priorities, values, and child-rearing practices are incorporated into quarterly child objectives, teaching practices, and assessment of progress (Vismara et al. 2009a). Parents learn to incorporate the ESDM approach into caretaking and family routines as well as play activities. The transmission process involves a coaching relationship between provider and parents. The goal of parent coaching is to promote the child's social-communication and cognitive development and to promote parent-child communication and play, to foster parents' feelings of competence and

confidence in their interactions with their child, and to maximize child learning opportunities (Vismara et al. 2009b).

Efficacy Information

DM effects as a group preschool intervention were first examined in a series of papers examining pre-post test data (Rogers and DiLalla 1991; Rogers and Lewis 1989). Significant accelerations in developmental rates of young children with autism were found in cognition, language, reduction in autism symptoms, symbolic play, and social engagement. As a group, the children with autism doubled their developmental rates while in active treatment. Four independent replications of the model (Rogers et al. 2006) demonstrated significant accelerations of developmental rates within 6 months of implementation. These studies suggested that the DM has the capacity to affect development in many areas.

The first study of the DM as an individually delivered intervention used a single-subject design which randomized minimally verbal preschoolers to either the DM or the PROMPT treatment (Rogers et al. 2006). PROMPT is a method for treating apraxia of speech developed by Deborah Hayden (formerly Chumpelik) and her colleagues in the early 1980s. The technique was originally developed for adults suffering apraxia of speech secondary to brain injury (Chumpelik 1984). PROMPT involves physical stimulation of the speech motor system during intentional communicative vocalization or verbalization. The DM delivery involved 1 h of individual treatment and parent training weekly and daily 1-h home parent practice sessions for 12 weeks. Eighty percent of children in both approaches acquired functional speech at a frequency of 10–200 words per hour (Rogers et al. 2006).

The most important outcome study of ESDM used a randomized controlled design with 48 toddlers with autism, ages 18–30 months (Dawson et al. 2010). The ESDM group received 15 h per week of individual home treatment over a 24-month period, as well as 4 h per month of parent coaching. The comparison group received

a variety of community interventions for the same period of time. Over a 24-month period, the ESDM group demonstrated large and highly significant increases compared to the community intervention group in overall IQ gains, receptive and expressive language gains, and adaptive behavior functioning. These differences were not likely due to the number of intervention hours delivered, since the two groups' intervention hours were very similar. Follow-up studies of these children will determine the trajectory of their development 5 years after this study. A multisite replication of this study involving 100 12–24-month-olds is ongoing.

Outcome Measurement

Child learning objectives in all core developmental areas are written every 12 weeks. Child progress is monitored after every 15 min of treatment on “daily data sheets” developed from the child's short-term objectives. Measurable progress is expected on every objective within a 1–2-week period and mastery of all objectives is assessed every 12 weeks. New objectives are written and broken down into small teachable steps, and new data sheets are developed at these 12-week intervals. Annual progress is measured through a battery of standardized tests, involving development, adaptive behavior, vocabulary and gesture use, and the Autism Diagnostic Observation Schedule (ADOS; Lord et al. 1999) to measure the number and severity of autism symptoms.

Qualifications of Treatment Providers

ESDM treatment providers have completed multiple levels of training and have received certification as ESDM therapists. Those who coach families to use ESDM at home have also been certified as ESDM parent coaches, and those who train others to use ESDM are certified as ESDM trainers. Training is available at multiple sites in the USA and abroad, and those seeking training can find information on the ESDM website. All ESDM published studies were

carried out by trained and credentialed therapists and staff. Professionals from a wide number of disciplines may be trained as ESDM therapists. Those professions include occupational therapy, physical therapy, speech and language pathology, early childhood education, early childhood special education, clinical child psychology, school psychology, and other professions that include background in early childhood development as part of the graduate curriculum. Those without a professional credential cannot be certified as an ESDM therapist, though they may work under the training and supervision of an ESDM-credentialed therapist.

The ESDM was developed to be provided by a team of childhood professionals with training and experience in early autism intervention from a variety of disciplines. The team leader is credentialed in their profession and as an ESDM provider and is responsible for a variety of tasks: working with the parent to assess the child's needs and strengths; developing short-term objectives and breaking them down into teaching steps; delivering the intervention and supporting the parent to do so; training and supervising any non-licensed persons who are helping deliver ESDM; and keeping and analyzing data to assure child progress or to adapt the intervention methods to improve progress.

Parents learn to deliver ESDM at home from their team leader, since the embedding of ESDM techniques in play and caretaking routines is necessary for optimal progress. Materials are available to help parents adopt the techniques, and a manual is currently being published (Rogers et al. 2012).

For children who are receiving many hours of ESDM weekly, well-trained paraprofessionals may deliver the intervention under the ongoing supervision of the team leader. Paraprofessionals learn to deliver the model at appropriate levels of fidelity of intervention under the supervision and guidance of trained ESDM professionals. Fidelity should be checked frequently when multiple adults are delivering ESDM. Team meetings should occur at least every 2 weeks to review child progress, discuss the intervention plan, and assure intervention consistency.

While printed ESDM materials are available to the public, it is usually necessary to attend specific training to master the ESDM. Those wanting to learn ESDM can access training materials through the MIND Institute website. Information about training workshops in various cities and countries is also posted.

Early-Life Exposure to Antibiotics and Autism Spectrum Disorders

Jan Łukasik, Bernadeta Patro-Gołęb, Andrea Horvath and Hania Szajewska
Department of Paediatrics, The Medical University of Warsaw, Warsaw, Poland

Definition

Autism spectrum disorders (ASD) encompass a range of neurodevelopmental disorders, which include autism and Asperger syndrome. Early-life exposure to antibiotics includes their use by pregnant mothers (prenatal) and children during early childhood. The gut microbiota refers to the many species of microorganisms living in our intestine.

Historical Background

One of the key subjects in the field of human microbiota research is its connection to neurodevelopmental and psychiatric conditions. A number of studies have confirmed that individuals with autism have different intestinal microbiome compositions compared to those of healthy individuals (Kraneveld et al. 2016). Interactions between the gastrointestinal tract and the central nervous system, which are explained by the so-called microbiome-gut-brain axis model (Cryan and Dinan 2012), form the rationale for investigating the gut microbiota as a possible contributor to the pathogenesis of autism. According to the aforementioned model, disturbed immune response and release of cytokines triggered by microbiota alterations may affect function of the central nervous system. Antibiotics are proposed as a potential causative factor for this phenomenon, since they are known to disturb the composition of microbiota in infancy (Yassour et al. 2016).

The first reports that linked autism symptoms with antibiotic-associated microbiota alterations were published in the early 2000s. In 2000, Sandler et al. described a group of 11 autistic children who developed ASD symptoms and chronic diarrhea shortly after use of broad-spectrum antimicrobials. Subsequently, the children underwent an 8-week course of oral vancomycin therapy, after which a transient improvement was observed in their behavior and communication skills (Sandler et al. 2000). A case series published 5 years later described 206 children who reportedly received multiple courses (mean number per child: ~12) of antibiotics for multiple bouts of otitis media before the occurrence of autism symptoms (Fallon 2005). The aforementioned reports lacked control groups – or, in case of the 2005 study, any statistical analysis – therefore, their findings were insufficient to allow clear conclusions to be drawn. However, after these first claims of an association between early-life antibiotic exposure and the occurrence of autism, a number of larger observational studies with analytical design were performed.

Current Knowledge

The largest studies on the subject performed to date derived data from Danish and Canadian population-based cohorts. A study of more than 95,000 Danish children (Atladdottir et al. 2012) reported a borderline significant increase in the risk of ASD after use of any antibiotics during pregnancy. A slightly stronger association of prenatal antibiotic exposure with the risk of ASD was reported for the use of sulfonamides, whereas macrolides were associated with a higher risk of infantile autism. On the other hand, the authors pointed out that multiple testing could be a potential limitation of the study. In total, more than 100 comparisons were made; therefore, the few statistically significant associations could be chance findings.

Early childhood antibiotic exposure as a risk factor for ASD was investigated in a study of more than 200,000 Canadian children (Hamad et al. 2018). There was a trend toward a reduced risk of ASD in children exposed to any antibiotics during the first year of life; however, no such association was found in an analysis among siblings. In another study of more than 650,000 Danish children, a slightly increased risk of autism was observed in children exposed postnatally to penicillin or to broader-spectrum antibiotics compared to children unexposed to antibiotics (Axelsson et al. 2019). In this study as well, a significant association was no longer observed in the sibling model. Another cohort study of more than 780,000 Danish children reported a slightly increased risk of autism after use of broad- and moderate-spectrum antibiotics (Wimberley et al. 2018). However, the population of this study overlapped with the population of the previous one. Moreover, the findings were not explored in sibling analysis. Data from the aforementioned cohort studies do not support a clinically significant association between early childhood antibiotic exposure and the development of ASD. Authors of pointed out that the borderline significance of the results and lack of confirmation of findings in sibling analyses contribute to ambiguity of the results.

Additionally, the association between ASD and early-life antibiotic exposure has been evaluated in a number of smaller case-control studies. In some of them, no significant associations were found (George et al. 2014; Guisso et al. 2018; Isaksson et al. 2017). In others, a slightly increased risk of ASD was reported after use of various antibiotics (Bittker and Bell 2018; Grossi et al. 2018; Niehus and Lord 2006).

In 2019, a systematic review summarized the available evidence on pre- and postnatal antibiotic exposure and subsequent risk of ASD (Lukasik et al. 2019). This review included 11 observational studies, consisting of cohort studies and case-control studies. The results of the included studies were conflicting, and the reported significant associations were usually of borderline significance or were derived from case-control studies with a considerable risk of bias. Moreover, a meta-analysis performed by the authors did not yield any statistically significant results. The authors of the review concluded that the included articles do not provide strong support for the hypothesis that early-life antibiotic exposure is associated with subsequent development of ASD.

Future Directions

As of now, there are not enough available data to conclusively rule out or confirm the notion that antibiotic use is a risk factor for ASD. It needs to be emphasized that this field of research faces a number of significant difficulties. Firstly, it is hard to discern whether the observed associations are due to the antibiotics themselves or are due to the underlying infections. Antibiotics are usually used to treat an infection, so controlling for this confounding factor creates a serious challenge for the investigators. This obstacle could be partially overcome by identifying patterns of microbiota disturbance associated with ASD. However, even though some characteristic microbiota alterations have been identified (Rosenfeld 2015), it is unknown if a definable pattern of “ASD microbiome” exists. Moreover, even if

such a pattern is discovered, it would be difficult to link it to the impact of a particular antibiotic, as effects of antibiotics on microbiota are not specific (Yassour et al. 2016). To acquire a definitive answer to the question as to whether an antibiotic-ASD association exists, more studies are needed – both in epidemiology and in the field of the human microbiome.

Eating Disorders

Annemarie van Elburg
Child and Adolescent Psychiatry, Rintveld Center
for Eating Disorders, Altrecht Mental Health
Institute, University Medical Center Utrecht,
Utrecht, The Netherlands

Synonyms

Anorexia; Bulimia nervosa; Pica; Rumination disorder

Short Description or Definition

Eating disorders like anorexia and bulimia nervosa (AN/BN) are complex psychosomatic disorders of unknown etiology, primarily affecting adolescent girls and young women. They are characterized by aberrant patterns of eating behavior and weight regulation which in AN result in weight loss and endocrine abnormalities such as amenorrhea, disturbances in attitude and perception about weight and shape, and an intense fear of gaining weight. Patients are classified AN according to the Diagnostic and Statistical Manual 4th edition (DSM-IV, American Psychiatric Association 1994) when they are incapable to maintain a body weight above a minimal normal level ($\text{BMI} < 17.5 \text{ kg/m}^2$ for adults), demonstrate an intense fear of becoming fat, have disturbed perceptions of body shape and size, and (after menarche) show amenorrhea. Two subgroups are classified, the restricting type in which weight loss is the result of dietary restriction and the binge/purge type in which periods of bingeing or purging and dietary restriction coexist. When compared to other psychiatric disorders, AN has the highest mortality rate: 10–15%. BN shares many features with AN but for the weight loss.

Accompanying symptoms, such as perfectionism, obsessive-compulsive behavior, and social

anxiety, are observed in many but not all patients. This characteristic cluster of personality and temperamental traits often persists after recovery and has been described preceding the onset of disease as well. In addition, a large proportion of AN patients displays abnormally high physical activity levels and over exercises, although estimations vary from 31% to 80% because of definition difference.

Although the etiology of AN is as yet unclear, a combination of cultural, social, psychological, genetic, and biological factors is implicated: “Genes load the gun, environment pulls the trigger” (Bulik and Tozzi 2004).

Other problems sometimes observed include pica (eating of nonnutritive substances) and rumination (repeated regurgitation and rechewing of food).

Categorization

The combination of eating disorders with autism spectrum disorders is uncommon and little researched. Most studies focus on disturbed eating behavior in autistic children. Some studies find that the behaviors themselves also occur in normally developing children, but much less often. Normally developing children seem to outgrow these behaviors while children with a disorder in the autistic spectrum do not. Two-thirds of parents of children with autistic spectrum disorder describe picky eating in their children. The most frequently described eating disturbances are food neophobia and selective eating; other disturbances such as pica and rumination seem to be more common in autism associated with mental retardation.

Problems with eating – including particular food refusal, food fads, pica, hoarding, overeating, and various degrees of anorectic behaviors, including complete food refusal and compulsive ordering of food on the plate – are extremely common in autism. Pica and rumination may also be seen.

Epidemiology

The total incidence of AN in the Netherlands is relatively stable. In the period of 1995–1999, the

age and sex adjusted incidence rate was 7.7/100,000. Interestingly, the incidence in female 15–19-year-olds (as well as 10–14-year-olds) almost doubled when compared to 10 years before, indicating that the onset of the disease is currently taking place at a younger age (Van Son 2006). Average prevalence rates of AN in Europe appear stable at 0.29% (Hoek and van Hoeken 2003).

In a controlled study of representative cases of anorexia nervosa, 18% had an autism spectrum disorder (4% autistic disorder, 6% Asperger syndrome, and 8% atypical autism), both at the time of onset of the eating disorder (around 15 years of age) and 5 and 10 years later.

Natural History, Prognostic Factors, and Outcomes

Recovery of anorexia nervosa in general takes a long time; it has been reported that stable physical recovery is reached after on average 4.7 years and psychosocial recovery after 6.6 years. Final outcome figures of AN leave room for improvement. According to Steinhausen (2002), 20.8% (0–79%) of AN patients remain chronically ill, and 5.3% (0–22%) die as a consequence of starvation or by suicide. Chances for recovery range from 0% to 92%, averaging at 46.5%. Data in younger patient groups are more optimistic, reaching about 60% for complete recovery.

Clinical Expression and Pathophysiology

A large number of studies indicate that there may be a propensity for underweight or comorbid eating disorders. One-fourth of male cases with autism of Asperger syndrome had a BMI in the 5th percentile or below, though no eating disorder diagnoses were justified. No association was found between autistic behavior and BMI, but there was a small effect of hyperactivity.

Disturbed Eating Behaviors in ASD

Rumination, the repetitive regurgitation of recently ingested food into the mouth with

subsequent spitting or remastication and swallowing, has been described in adolescents and adults with autism. It can lead to tooth erosion caused by gastric acid, as well as malnutrition and esophageal abnormalities.

Pica, or eating inedible nonfood substances, seems to be a problem especially in institutionalized cases of mental retardation associated with autism. When present, it is potentially dangerous and difficult to treat. Pica may result in gastrointestinal problems or poisoning with heavy metals. Overeating.

Eating disturbances in Asperger, teenage boys: selective eating and hyperactivity resulting in low body weight. In adults with ASD and normal intelligence, health reasons are often given for special diets.

Psychogenic polydipsia (excessive water intake) presents a problem in autism with mental retardation.

Food neophobia is the avoidance of all new foods. This has been linked to selective eating but should be treated separately.

Selective eating (eating only ten foods or fewer, sometimes food of a special color, texture, or brand, avoidance or refusal of new foods)

Proposed Underlying Mechanisms in Disturbed Eating Behaviors in ASD

Sensory abnormalities: Hyper/hyposensitivity to auditory, visual, tactile stimuli and to smell and taste may play a large part in mealtime behaviors.

Interests: Restricted and intense ideas and interests, for example, having strict ideas about the appropriate amount of food required without paying attention to feeling of hunger or satiety, fixating on ideas of which food are healthy etc.

Routines: Ritualized eating routines.

Social interaction and other skills involved in dining: Eating with other people is an ordeal for many persons with autism because of doing several tasks simultaneously, leading to unusual table manners in some cases.

Motor functioning: Motor problems are common in ASD, which can make the use of knife and fork difficult.

Gastrointestinal problems: A high rate of gastrointestinal symptoms is reported in children with

ASD compared to peers, in most cases without known medical causes.

Anorexia nervosa: It is suggested that ASD and AN share some features, namely, obsessiveness, insistence on sameness, and social impairment. It is suggested that a subgroup of AN has a cognitive style very similar to ASD.

Gender issues: AN and Asperger are both considered to be specific to one gender; perhaps if the criteria of AN would be reconsidered with the male population in mind, and the Asperger criteria would include more behaviors and attitudes more appropriate to females, much more overlap would occur.

Evaluation and Differential Diagnosis

Evaluation and assessment vary depending on the nature of the eating problem. In all cases, a careful search for possible contributory factors (environmental, associated medical conditions, and so forth) is indicated. Weight loss and eating problems can be observed in various disorders (e.g., depression), and sometimes unusual beliefs about food or eating are seen in other psychiatric conditions (e.g., schizophrenia). Diagnosis can be more complicated in individuals with autism and with cognitive disability.

Treatment

Treatments vary depending on the specific of the situation and the nature of the difficulty. Some syndromes of intellectual disability are associated with eating problems. For pica and rumination disorder, various behavioral procedures have been used. In younger children, it is important to be sure that other medical problems or environmental factors do not complicate the situation. In anorexia nervosa and bulimia nervosa, treatment is typically multifaceted with outpatient treatment preferred if possible. Pharmacological treatments may be combined with cognitive behavior therapy approaches depending on the specific situation.

ECHO Autism STAT

Micah O. Mazurek
Curry School of Education and Human
Development, University of Virginia,
Charlottesville, VA, USA

Definition

ECHO Autism STAT is a training program for primary care providers (PCPs) that combines hands-on training in autism diagnosis with ongoing virtual mentorship using the Extension for Community Healthcare Outcomes (Project ECHO) framework.

Historical Background

Early identification and diagnosis of autism spectrum disorder (ASD) are essential for facilitating access to intervention and services. Younger age at entry to intervention is associated with greater improvements across developmental domains for children with ASD (MacDonald et al. 2014; Perry et al. 2011; Smith et al. 2015; Vivanti et al. 2016). However, many children in the United States experience significant diagnostic delays, waiting an average of 3–6 years between first concerns and ultimate diagnosis (Baio et al. 2018; Sheldrick et al. 2017; Oswald et al. 2017). This has resulted in large-scale federal and professional efforts to prioritize early identification of ASD (Filipek et al. 2000; Healthy People 2020; Interagency Autism Coordinating Committee 2017; Myers et al. 2007).

Despite these efforts, the average age at ASD diagnosis remains between 4 and 7 years for children in the United States (Baio et al. 2018). Shortages of healthcare providers with training in autism have contributed to these delays, with many local communities having no access to autism specialists. Lack of local autism expertise, long wait lists at specialty centers, and high costs of services have rendered best-practice care inaccessible for many families. Underserved children and families are disproportionately affected by these barriers. Children from families with low income or socioeconomic status, those living in rural areas, and those from minority racial and ethnic groups face even greater diagnostic delays (Fountain et al. 2011; Mandell et al. 2010; Mandell et al. 2002; Rosenberg et al. 2011).

In 2007, the American Academy of Pediatrics (AAP) published guidelines recommending that autism screening be conducted at regular well-child visits in order to help expedite early diagnosis for all children (Myers et al. 2007). However, physician compliance with these guidelines has remained remarkably poor (Arunyanart et al. 2012; Keil et al. 2014; Self et al. 2015). Pediatricians and other primary care physicians report receiving very little formal training on autism during medical school or residency training (Fenikilé et al. 2015; Finke et al. 2010), and a

lack of knowledge about autism and unfamiliarity with appropriate screening tools has been identified by PCPs as primary barriers to screening implementation in their practices (Fenikilé et al. 2015; Self et al. 2015). Even when children are appropriately screened and referred for further evaluation, significant wait times at specialty centers contribute to additional diagnostic delays. Given the importance of early intervention for young children with ASD, new models are needed to reduce diagnostic bottlenecks and to improve access to early diagnosis in local communities.

Building local expertise among community-based providers who serve young children and families has the potential to reduce diagnostic delays and disparities for underserved families. Primary care providers (PCPs) offer accessible and integrated healthcare services and are tasked with conducting developmental surveillance and screening for all children. As such, they are perfectly positioned to help close the gap between first concerns and diagnosis, particularly if provided with additional knowledge and tools for ASD assessment.

Current Knowledge

The ECHO Autism STAT program was developed to reduce diagnostic delays by training community-based PCPs in underserved areas in screening and diagnosis of young children at highest risk for autism (Mazurek et al. 2019). The program combines hands-on training in standardized tools with ongoing virtual mentorship and practice, thus facilitating both timely diagnosis and appropriate referral for comprehensive assessment when necessary. The program builds upon and extends the technology-based Project Extension for Community Healthcare Outcomes (Project ECHO) framework. Project ECHO was originally developed to increase access to treatment of hepatitis C virus infection by training community-based PCPs (Arora et al. 2010; Arora et al. 2011) and was more recently adapted for autism (Mazurek et al. 2017). Project ECHO's technology-based mentorship model reduces geographic barriers to specialty knowledge and is

based on adult learning principles that maximize practical application and knowledge retention.

The ECHO Autism STAT model (Mazurek et al. 2019) follows a multitiered approach to diagnosis in which the assessment method is determined by the child's symptom presentation and complexity. The program was designed to train PCPs in diagnosis of young children whose symptoms are unambiguous and in appropriate referral for complex cases that require more comprehensive assessment. The program begins with a 1.5-day face-to-face training focused on autism assessment and administration of the Screening Tool for Autism in Toddlers and Young Children (STAT), a standardized play-based observational autism assessment tool for very young children (Stone et al. 2000). After the in-person training, PCPs join bimonthly 90-min ECHO Autism STAT sessions for 12 months, during which participants are connected by videoconference with one another and with an interdisciplinary team of autism experts. The expert team includes a pediatrician, a psychologist, a child and adolescent psychiatrist, a social worker, a dietician, and a parent of a child with autism. Each session includes a brief didactic presentation, case-based learning (during which PCPs present their own cases for discussion and co-management), and collaborative guided practice. The curriculum focuses on best-practice guidelines for diagnosis and treatment of ASD, with specific emphasis on symptom identification, screening tools, diagnostic interviewing, differential diagnosis, parent support, community resources, and management of co-occurring symptoms.

Participants in the program receive in-depth training in administration and interpretation of both Level 1 and Level 2 autism screening and assessment tools. Strategies for implementation of general developmental and autism-specific screening tools are discussed throughout the 12-month program, and participants also engage in quality improvement efforts to track their success in implementation of these tools in their practices. For example, Level 1 tools include the Ages and Stages Questionnaire, third Edition (ASQ-3); the Parents' Evaluation of Developmental Status: Developmental Milestones (PEDS-

DM); and the Modified Checklist for Autism in Toddlers, Revised (M-CHAT-R), with Follow-up Interview. Following the in-person training on the STAT (a Level 2 tool), participants are required to achieve reliability in STAT coding and administration (including submission of videotaped recordings of their own administrations). Participants also receive training on diagnostic interviewing for autism and on providing feedback and guidance to families. Written and online guidelines, resources, and toolkits are made available to PCPs through a secure online portal.

In addition to formal didactic presentations, a large portion of the teaching and mentorship provided during ECHO sessions occurs within the context of case-based learning. The majority of time within each ECHO Autism STAT session is dedicated to discussion of de-identified cases presented by PCPs using a standard case presentation format. During the first 6 months of the program, PCPs discuss cases for which this is a concern of autism (screening) or cases for which there is a concern about symptom management. The expert team and all participants have opportunities to ask clarifying questions to learn more about the case and the presenter's approach to date. Following this discussion, the expert team provides evidence-based recommendations and guidance to the PCP, building knowledge and expertise among all participants. PCPs may then re-present cases during later sessions to receive feedback and ongoing coaching. Over time, participants form a collaborative learning community in which expertise is shared and developed. In contrast to traditional telemedicine approaches, the ECHO model enables PCPs to retain responsibility for managing their own patients with guidance from the specialist team. Through this process, PCPs acquire knowledge, skills, and self-efficacy that is directly applicable to their own practice.

During the second 6 months of the ECHO Autism STAT program, PCPs who have achieved reliability on the STAT are eligible to present cases for diagnostic consideration. For these cases, PCPs follow a specific ECHO Autism STAT diagnostic algorithm to assess young children who are determined to be at risk for ASD following routine

surveillance and/or Level 1 screening. Rather than referring the child to a specialty center for diagnostic evaluation, PCPs administer the STAT and a semi-structured diagnostic interview for autism in their own practices. PCPs then present the results of the evaluation during an ECHO Autism STAT session. Cases are discussed with the expert team and all participants and are determined to either (1) clearly meet criteria of a diagnosis of ASD or (2) require further evaluation due to subtle or complex symptom presentation. This risk-stratified process for diagnostic determination facilitates rapid access to diagnosis and intervention for children at highest risk for autism while fostering access to more comprehensive assessments when warranted.

Future Directions

The results of the initial ECHO Autism STAT pilot study indicated improvements in PCP practice and self-efficacy and demonstrated that the model is feasible for enhancing local access to early diagnosis for children at greatest risk for ASD (Mazurek et al. 2019). Future directions for the evaluation of this program should include validation of PCP diagnostic determination as compared to comprehensive assessment with gold-standard autism diagnostic instruments. Additional work is needed to develop and validate a process for verification of PCP mastery, competence, and readiness to complete evaluations independently of the ECHO Autism STAT program. An examination of effectiveness of this model in reducing time to intervention, increasing access to care, and reducing cost and burden for families of children with ASD will also be important.

The ECHO Autism STAT program represents one approach for reducing healthcare disparities for underserved children with or at risk for ASD by increasing local diagnostic expertise. Future work should continue to explore novel and flexible models that leverage technology to infuse autism expertise into local communities. Although building capacity for early identification and diagnosis in primary care is one important avenue, additional large-scale efforts are also

needed to support community-based practitioners in caring for children with and at risk for ASD across settings and service systems.

Echolalia

Moira Lewis
Speech-Language Pathologist, Marcus Autism
Center Children's Healthcare of Atlanta, Atlanta,
GA, USA

Synonyms

[Delayed echolalia](#); [Imitative speech](#); [Immediate echolalia](#); [Scripting](#)

Definition

Echolalia, either immediate or delayed, is the repetition of sounds, words, phrases, or larger chunks of language. It is a repetitive pattern of language that does not necessarily contain meaning, nor is it directed to others for a specific purpose. Echolalia can be seen in individuals with various developmental disorders, including autism, Tourette's syndrome, aphasia, and schizophrenia.

Typical children who are developing language may demonstrate echoed speech between the ages

of 12–30 months of age. Lovaas (1981) reported that in typically developing children, echolalia peaks at approximately 30 months. This pattern tends to fade as a child's vocabulary and variety of language forms develop. For children with autism, however, the pattern can persist beyond 30 months and their repetitive talk may often be related to areas of special interest, media, or other environmental factors. Children may echo language used by people in their environment, or language heard within TV or songs.

Research (Prizant and Duchan 1981) has shown that children and adults with autism may use echolalia for a variety of communicative purposes, such as a way to process language and improve their comprehension, as a means to initiate a conversation, or to form a reply. Echolalia is also thought to be a way for some children to cope with and “tune out” stressful situations.

Immediate echolalia is the repetition of a word or phrase directly following its utterance by another. For example, a child may repeat a question mother has just asked (Mother: “Do you want juice?” Child replies, “Do you want juice?”). Delayed echolalia is the repetition of words and phrases heard at some previous time, for example, a child may repeat an announcement heard at school the previous day (“Today we will be having a fire drill”). As spontaneous language improves in children with autism, echolalia tends to decrease, as it does among typically developing children.

Ecological Model of Autism

Jeffrey Danforth

Department of Psychology, Eastern Connecticut State University, Willimantic, CT, USA

Ecological Inventory

Frances L. Kohl

Department of Special Education, University of Maryland, College Park, MD, USA

Definition

An approach to identify functional, age-appropriate curriculum content a student needs in specific environments within the following curriculum domains: personal management, community, vocational, leisure, and school. The process involves five phases: (1) identify the curriculum domains, (2) identify current and future natural environments within each curriculum domain, (3) identify the sub-environments within the natural environments, (4) inventory the relevant tasks within each sub-environment, and (5) analyze each task into component skills needed to perform the task from start to finish.

Definition

The ecological model of autism studies the behavior of individuals with autism within the context of many levels of environmental influence and assumes bidirectional influences between (a) the person and these environmental influences and (b) the many environmental levels. Context refers to the wide range of system levels that influence individuals with autism, including the immediate responses of caregivers and family, school, local community, as well as broader cultural, economic, and political practices. Some variables have a direct immediate impact, and some more distal variables have an indirect impact. With the ecological model, the appropriate unit of study is the interaction of the environment and individual, the organism-environment system; “autism is not a static condition existing within a person, but a developmental process that can only be understood as taking place through the interaction of person and environment” (Loveland 2001, p. 22). An essential element of the ecological model of autism “is that every level of the ecological system is interconnected and thus can influence all the other subsystems. These influences are reciprocal rather than unidirectional” (Weiss et al. 2010, p. xxv). Ecological models attempt to explain not only the immediate impact of caretaker/client interaction on the behavior of the individual with autism but also the impact of social and economic policies and the impact of those variables on one another.

Ecological Model

► [Monotropism: An Interest-Based Account of Autism](#)

Historical Background

The ecological model of autism is a component of the broader interactional model that assumes many variables interconnect to produce an

outcome. The transactional model is one type of interactional model used to study development. The primary assumption is that development is the outcome of dynamic interactions between the individual and many layers of the environment. The context of the environment ranges from variables near the individual to those that are quite distant (Wicks-Nelson and Israel 2009). One type of transactional model is the ecological model. The comprehensive ecological systems theory emphasizes the importance of the context in understanding a person's behavior (Bronfenbrenner 1979; Gibson 1979). Early behavioral models emphasize contextual variables such as discriminative stimuli and setting events, but the ecological model of autism analyzes a broader range of environmental variables, from microsystems that include physical space, lighting, and noise in the teaching environment to broader cultural and historical events and the interactions between these variables.

Current Knowledge

The ecological approach to treatment of autism requires a multidisciplinary treatment team to tailor services to the specific needs of the individual and their caretakers, so treatment is not limited to the individual and their family. Intervention extends to any ecological or contextual variable that affects the individual with autism.

The ecological theory of autism may be conceptualized as a multidimensional series of concentric circles having the individual with autism in the middle (Zigler and Stevenson 1993). Many investigators consider the critical autistic feature the inability of the individual to understand what others think or feel, a weakness in theory of mind. Broader developmental characteristics include observable operant behavior (both desirable and undesirable), cognition, neurological conditions, emotional behavior and mood, social behavior, communication skills, motor behavior, medical conditions, and sensory deficits. Molecular behavior includes the form of the response, duration, latency between antecedent and behavior, the

time between responses, and the intensity of the response. The individual's personal goals, preferences, and strengths are important considerations. The ultimate criterion "emphasizes that assessment efforts and intervention objectives specifically target behavior that will be functional for the individual with a disability in real environments" (Powers 2005, p. 818).

The *microsystem* is the first level of the environment. This includes the minute-by-minute and day-to-day interactions between the individual with autism and caregivers (parents and teachers), peers, and siblings as well as the daily settings and physical structure of home, school, and community. Within these systems, it is critical to recognize the bidirectional effects of behavior; caretakers influence people with autism, but the stress of autistic behavior also influences caretakers, and stressful caretaker reactions can in turn affect the autistic behavior. For example, in response to unusual social and emotional behavior, caretakers of children with autism are more directive and may even smile less toward the children. Loveland (2001) contends the socially inappropriate behavior of individuals with autism is a product of both neurobiological impairment and the abnormal reactions of significant others to the unusual social behavior. Furthermore, the abnormal feedback of others may affect neurological development (e.g., synaptic pruning) in the young child whose behavior then becomes more atypical, with the cycle revolving. At this level, the ecological unit of analysis may also examine coercive processes (Binnendyk et al. 2009; Patterson 1982). Such analyses may evaluate whether inappropriate behavior is the outcome of positive reinforcement by attention, negative reinforcement by caretaker acquiescence, or exacerbated by repeated commands or reprimands for trivial behavior.

The determination of target behavior strengths and weaknesses selected for treatment is an important component, as practitioners must also consider whether the selected targets are meaningful to the family, day-to-day caretakers, and the community (Kazdin 1977). Behavior analysis of the microsystem would include operational

definitions of selected target behaviors, distal setting events, antecedents that immediately precede the behavior (discriminative stimuli), and consequences that immediately follow the behavior (reinforcers and punishers). Ecological validity, or ecological assessment (Powers 1997), identifies whether the selected prosocial target behaviors are functional in the person's day-to-day environment. For generalization of behavior across time and settings, selected target behaviors must be naturally functional (i.e., reinforced by the natural community) within the microsystem, and care is taken to identify obstacles in the natural environment that may punish the selected behavior.

The physical structure of home, school, and community takes into account characteristics of the general setting such as large crowds, noise, and predictable schedules versus chaotic routines that may influence autistic behavior. For example, in the context of challenges presented to individuals with autism in the form of schedules and routines, Binnendyk et al. (2009) conceptualize the essential unit of analysis as the quality of parent-child interactions embedded within routines of everyday life. The quality of family interactions within these routines may have a "profound" impact on the child's development. Family-selected routines that have served as the basis for routine-specific treatment plans include bathroom routines, restaurant routines, dining at home, dining at a restaurant and fast food establishments, grocery shopping, family television time, and bedtime.

Other units of analysis go beyond the behavior of the individual person and require myriad sources of data from larger social systems. The next level of the environment is the *mesosystem*, representing the interactions across the individual's microsystem. Variables that influence the individual with autism include parents' marital strain, extended family relationships, the reciprocal relationships between parents and teachers, parents and siblings, teacher and school, etc. For example, interpersonal conflict between parents and teachers or parents and siblings may have an effect on the behavior of the individual with

autism, and if this were determined to be the case, an ecological approach will consider that conflict a variable that needs to be addressed as part of treatment. Sometimes, the highly sophisticated practices of treatment workers contrast with parent training intellectually limited family members at home. If these contrasting styles prevent adequate application of services in the home setting, then an ecological approach will consider that disconnect a variable that needs to be addressed as part of treatment.

Contexts that influence the child indirectly compose the *exosystem* of the ecological system. The exosystem influences the child indirectly by effecting institutions and people in the individual's microsystem. For example, a parent may lose a job or be transferred to employment in another state. The stress of parental unemployment or moving to another state with concomitant schedule and routine changes may influence the behavior of the individual with autism, especially an individual whose repertoire includes resistance to change or well-established rituals. Structural changes within social service agencies that provide counseling and family support may lead to new treatment workers who are required to relearn details of the family's goals and objectives and establish new relationships, all of which can affect the individual with autism. Other exosystems that do not include the person with autism but can influence them include parent social networks, socioeconomic status of the family and neighborhood, the availability of mental health services in the community, the availability of professional training in empirically validated practices for service providers, the availability of materials and human resources required to meet the needs of the child (Lovaas 2003), and the availability of follow-up care and respite as needed.

In recognition of the growing diversity of the family unit, an ecological analysis also includes a subjective understanding of a family's values and beliefs. This allows treatment plans to consider culturally sensitive interventions when collaborating with families, sometimes referred to as cultural competence (Lynch and Hanson 2004).

The broadest level of influence composed of the culture's values, the economy, political trends, and social policy is the *macrosystem*. Resources for the family and school, tolerance of individual differences, and general opportunities afforded individuals with autism are greatly influenced by the macrosystem. State and federal law has mandated a number of recent social policy trends. In 1990, the US Congress added the word "autism" to laws that guarantee special education services. The Individuals with Disabilities Education Act, the federal law pertaining to special education, was reauthorized in 1997 (National Dissemination Center for Children with Disabilities), and both of these acts have resulted in more educational/treatment services to children with autism and more inclusion in less segregated (and less restrictive) general school settings. At the same time, economic conditions in the 2010s may lead to reduced local school budgets and reduced educational services.

Many states in the USA have passed laws requiring state-regulated group health plans to include coverage for autism, and federal law prohibits insurance companies from refusing to issue or renew coverage for children because of pre-existing conditions including autism. The outcome for families of children with autism includes monetary saving and less emotional stress, with children eligible for a wide array of services.

The chronosystem signifies time both within the lifetime of the individual of interest and the historical context within which the person lives (Weiss et al. 2010). Over the course of time, the child and family's growth and learning can affect each of the above-described systems. Furthermore, the historical context within which the person lives influences the services available to that person. Compared with individuals living prior to 1980, much has changed for individuals with autism. One critical difference is how the definition of autism presented in the American Psychiatric Association's Diagnostic and Statistical Manual of Mental Disorders (DSM, American Psychiatric Association [APA], 1980, 1994, 2000) has changed. Although Kanner identified autism in the 1940s, it was not until 1980 that

criteria for autism were defined in the DSM. Since then, the phrasing to describe autism has become far less restrictive. The 1980 DSM required six mandatory criteria with phrasing that limited the number of people diagnosed with autism (e.g., "A pervasive lack of responsiveness to other people" in the 1980 DSM is replaced by "Lack of spontaneous seeking to share... achievements with other people"). In conjunction with the 1994 inclusion of Asperger's disorder in the DSM, the acknowledgment that autism can exist among people across the entire range of intelligence, and recent efforts to take advantage of neural plasticity by identifying and providing comprehensive treatment among the youngest children with autism, the number of people on the autism spectrum eligible for services has expanded greatly. Perhaps three fourths of those diagnosed with autism are accounted for by those diagnosed with milder variants (Chakrabarti and Fombonne 2001), and only 35 years ago, many of these people would not have been eligible for services.

Ultimately, ecologically sensitive interventions synthesize data from multidisciplinary sources to develop a holistic intervention that addresses the individual with autism, their caretakers, the physical structure of important settings, and cultural variables.

Ecological Validity

Erin Rotheram-Fuller

School Psychology, Department of Psychological Studies in Education, College of Education
Temple University, Philadelphia, PA, USA

Synonyms

External validity

Definition

Ecological validity is the degree to which experimental measures (i.e., settings, treatment agents, materials, behaviors) occur naturally and are representative of events that occur in everyday life or in the settings in which the skill or behavior is expected to be performed (Brewer 2000; Schlosser 2003). The results of an ecologically valid assessment are predictive of appropriate behavior in a free environment (Franzen 2000). Ecological validity is important for descriptive or demonstrative research (Brewer 2000) and is an aspect of external validity that is closely related to, but not to be confused with, social validity (Schlosser 2003).

Edinburgh Handedness Inventory

Janine Robinson

CLASS, Cambridgeshire and Peterborough NHS Foundation Trust, Fulbourn, Cambridgeshire, UK
NHS England, London, UK

Synonyms

[EHI](#)

Description

The Edinburgh Handedness Inventory (Oldfield 1971) is a measurement scale which is employed to establish hand dominance. The 20-item inventory contains a list of instructions to be carried out by the individual being assessed. Items are rated by direct observation of the individual's behavior or by self-report of everyday behavior. Oldfield developed a second, shorter version, namely, a 10-item inventory, and it is this form which has been used most often.

This brief quantitative measure has proved to be of use in neuropsychological, general, clinical,

and research fields. However, where the question of establishing laterality is critical, such as in research, the author has reported that this scale used on its own is not sufficient to determine cerebral laterality and is effectively best employed as a screening measure. Given its simplicity and brevity, it would be particularly useful where large populations are being assessed. The measure benefits from properties which provide a useful standard of comparison in the neuropsychological field. The EHI is the most widely used instrument to measure handedness, and this appears to have increased in recent years (Fazio et al. 2011; Fazio and Cantor 2015). Furthermore, the measure has been translated into a number of languages, and the psychometric properties of translated versions have been established (Albayay et al. 2019; Espirito-Santo et al. 2017; Yang et al. 2018).

Oldfield (1971) strongly urges clinicians and researchers to follow the instructions closely in order to ensure limitation of misinterpretation and to ensure the form is completed correctly. However, Fazio et al. (2011) found that the original instructions were in fact problematic and only 47.3% of individuals in their study were able to follow the instructions completely. By contrast, 88.2% of these individuals could successfully follow the instructions on a different measure with Likert-style presentation. The authors note that the level of education and the handedness of the participants significantly predicted their ability to adhere to the instructions which had clear implications for the use of the Edinburgh Handedness Inventory.

Where individuals are being required to complete the form (self-reporting rather than being observed in a clinical setting), they are presented with a typed sheet and instructed to provide information regarding age and biological sex. The original inventory asks whether they have ever had a tendency to left-handedness.

Individuals are then presented with a list of ten items to score. They are instructed to consider their hand preference for each activity, indicating with one plus (+) if the preference is for the left or right hand. If they are *indifferent*, a plus is placed in both L and R columns. "Where the preference is so strong that you would never try to use the other

hand unless absolutely forced to, put ++” (Oldfield 1971). Since some tasks require two hands (e.g., striking a match), they are asked to indicate the hand preference for the key object, e.g., the match. All items are scored unless the individual has no experience of a task or object at all. A laterality quotient (LQ) is obtained by

$$(R - L)/(R + L) \times 100$$

where R = number of ticks in the *right* column and L = number of ticks in the *left* column.

Interpretation of results:

Left-handed <40

Ambidextrous 40 to +40

Right-handed > +40

While the core instrument has remained in use, various authors appear to have made adjustments to the instructions and presentation of the form. In addition, some authors have added further questions, e.g., holding a computer mouse (Cohen 2008; Dragovic 2004b), holding a cup for drinking, and using a key to unlock a door (Cohen 2008). Williams (1986) proposed a revision of the EHI resulting in changes to the number of items tested – reducing these from ten to seven – and consistent with Dragovic’s suggestion (2004b), adding the item computer mouse. He argues that two items (opening a box and using a broom) have been discarded since new factor-analytic studies found these items to be low outliers when loaded onto the “handedness” factor. The computer mouse is viewed as a significantly “unimanual activity in today’s world” (Williams 1986).

The EHI (revised) proposes the adoption of a Likert-style format, thus reducing the wording in the instructions to “Please mark the box that best describes which hand you use for the activity in question.” For each item, the respondent hence selects from five possible options, namely, *always left*, *usually left*, *no preference*, *usually right*, and *always right*. The procedure for arriving at the laterality quotient (LQ) is by necessity adjusted and can be used to identify those individuals who are mixed-handed (LQ between +50 and 50). Scoring is as follows: “- 50” *always left*, “- 25”

usually left, “0” *no preference*, “25” *usually right*, and “50” *always right*.

Scores on the eight rows are summed to provide a score LQ* of -400 to +400. If the LQ* score is then divided by 4, an LQ of -100 to +100 is achieved, i.e., complete left-handedness to complete right-handedness as per the original EHI. With the revised scoring method, -200 to +200 becomes mixed-handedness. Williams describes a clinical observation that the mixed-handedness group may further divide into two, namely, clumsy or coordinated. He anticipates that the clumsy group may have an LQ* score of -200 to -1 and the coordinated group an LQ* of 0–200.

Historical Background

When first published in 1971, the Edinburgh Handedness Inventory was initially named the Edinburgh Inventory (Oldfield). Previous assessment of handedness relied on either (a) observation of the individual carrying out tasks (seminovel) with left or right hands separately or (b) posing a number of questions about day-to-day activities and the hand use in these. In the former, the individual’s performance may be rated on time and/or error, enabling the calculation of an index of handedness.

The EHI has been used extensively in research (Boucher 1977; Dragovic 2004a, b; Cohen 2008; Edlin et al. 2015; Escalante-Mead et al. 2003; Fazio et al. 2011; Fazio and Cantor 2015; Williams 1991). Oldfield developed a 20-item and a 10-item version of the EHI. When the 10-item version was compared to Annett’s 12-item scale (1970), Williams found that, owing to the instructions, the EHI produced more “either hand” responses when usually the “left hand” would be the response (1991). He suggested that where neuropsychological researchers were looking to detect any degree of left-handedness, the questionnaire by Annett might be preferable.

While the EHI has remained a well-used instrument to establish handedness, it has been adapted by a number of authors, primarily adjusting the

presentation of the recording system and simplifying the instructions which have been deemed too complicated and potentially confusing for testees (Dragovic 2004b; Fazio et al. 2011; Cohen 2008). However, Edlin et al. (2015) conducted a review of 899 articles (1998 to 2012) citing use of the EHI and found highly variable usage of the measure and ad hoc adaptations rendering replication of research challenging.

Lateralization in autism has been of interest to scientists for many years, and the EHI has been employed in studies researching cerebral dominance and language development in individuals with autistic conditions (Boucher 1977; Froehlich et al. 2011; Williams 1986, 1991).

Psychometric Data

The Edinburgh Handedness Inventory has been refined since the original 20-item questionnaire in 1971. Oldfield discarded those items found to be redundant or inappropriate, given the purpose of devising a measure that would have universal application. He conducted a study of the 20-item inventory on 1,100 students. Analysis of items on the basis of biological sex, socioeconomic, and cultural factors resulted in ten items being discarded, leaving the inventory in its current form. On analysis of 1,027 responses (360 males and 667 females) where a score < 0 denotes left-handedness, 10% of males and 5.92% females scored < 0 (chi-squared = 6.21, $p < 0.02$). The authors noted the difficulties conducting statistical analyses on the data owing to the nature of the frequency distribution (a U form with the left side only containing about 10% of the total population). Treating the sections separately with the LQ cut at zero, percentage cumulative curves could be represented as the “right-handed” and “left-handed” sections, respectively. While the “right-handed” section could be represented in decile values, the “left-handed” section was less regular. The author notes that larger numbers will be needed in future studies to establish larger frequency values for the left-handed group. Hence, decile values remain provisional.

In a study of hand preference in the parents of autistic children, a similar pattern of results was found with 5.9% males and 0% females using the left hand more than the right (Boucher 1977). In Oldfield's student sample, 10% of those who predominantly used their right hand showed a very marked (LQ = 95–100) or almost exclusive preference. In Boucher's study, 69.1% of males and females who preferred the right hand used this almost exclusively. “Pure” right-handedness was significantly different between the groups at the $p < 0.001$ level on Guilford's test of the difference between two proportions. These unexpected results were nonetheless confounded by concerns regarding the reliability of the EHI and the possibility that some participants did not fully follow the instructions. Evaluation of handedness in the autistic children of these parents, on the other hand, indicated a persistent, but slightly increased tendency of autistic children to use the left hand.

McMeekan and Lishman's study (1975) compared the EHI (10-item) with the 12-item Annett questionnaire. The test-retest reliability results were unexpectedly moderate (0.80), but Williams notes (1991) a number of potentially significant methodological factors which most likely affected the results. On retesting with the EHI, participants often changed the classification from strong to weak. Williams does state that the EHI has one particular difficulty in the procedure employed for deriving the laterality quotient (LQ). Employing the equation, $(R - L) / (R + L)$, it is possible to achieve an LQ score of 100 in two ways: if there are 10–20 ticks in the R column, but none in the L column. In other words, there is no ability to discriminate between degrees of right-handedness. The issue of weighting of inventory items is also of some concern with no justification for equal weighting of some items and double weighting of items scored with two ticks. Williams (1991) notes that Annett's designation of “primary” and “secondary” items facilitates more sophisticated statistical discrimination.

Fazio and Cantor (2015) compared the factor structure of the EHI with the Fazio Laterality Inventory (Fazio et al. 2013). They found the FLI to provide a more accurate measurement of

handedness. When tested in a population of atypical handedness, factor analysis of the EHI demonstrated a single factor loading, while factor analysis of the FLI elicited two underlying factors (eigenvalues >1 ; 5.74 and 1.39). The authors describe the factors as fine motor/ballistic movements and expressive/instrumental movements. They argue that while both the FLI and EHI have good face and construct validity in typical handedness populations, the former is more helpful in measuring handedness in populations that are associated with atypical handedness.

Clinical Uses

The Edinburgh Handedness Inventory (Oldfield 1971) is used to assess hand dominance in everyday activities. The measure may be rated by an observer or by the individual's self-reporting. The author viewed the latter as less reliable since individuals tend to overestimate the number of tasks carried out using the dominant hand. Nonetheless, for ease of use, clinicians and researchers predominantly employ a questionnaire-based assessment of handedness over performance-based measures (Williams 1991). Such questionnaires have demonstrated themselves to be highly correlated with behavioral measures (Chapman and Chapman 1987).

Establishing hand preference may shed light on how the brain matures. Laterality has been demonstrated to be of importance in autism spectrum conditions, language, mathematical, and musical ability.

For instance, in a study of early language disturbance and lateral preference (on the Edinburgh Handedness Inventory), researchers found that autistic individuals who had early language disturbance displayed more atypical cerebral dominance than neurotypical controls and autistic individuals who had had normal language development (Escalante-Mead et al. 2003). Results indicated that there was not in fact a greater incidence of left-handedness in autism, but rather a disturbance in the developmental process of establishing lateral dominance. An atypical pattern or delay in establishing cerebral dominance

may have implications for language development in autism.

The Edinburgh Handedness Inventory remains a valuable tool in clinical neuropsychology. Additional measures may contribute to further understanding of handedness in populations known to be neurologically atypical.

proper support. To ensure that children with ASD have access to this support, federal legislation requires that public schools provide eligible children with ASD an education that is adapted to meet their individual needs (Steedman 2007). Since students with ASD have different strengths and deficits, their educational programs may look very different. Researchers and professionals have used research, legislation, and professional experience to develop ASD program quality indicators (Alquraini 2011; Crimmins et al. 2001; Ruble et al. 2010). These indicators include comprehensive student assessment, ongoing progress monitoring, assessment-based and detailed individualized education plans (IEPs), individualized and appropriate curricula and instructional methods and activities, procedures for assessing and replacing challenging behaviors, qualified and appropriate school personnel, and high levels of family involvement (please see the section “Current Knowledge” for more information).

Definition

Autism spectrum disorder (ASD) is characterized by communicative, social, and behavioral impairments. Specifically, the two major categories of deficits are in social communication and repetitive behaviors (American Psychiatric Association 2013). These issues can make it difficult for children with ASD to succeed in traditional educational settings. However, many children can progress and even excel with the

Historical Background

In the past, students with ASD and other disabilities were often denied access to a public education. It was not until the 1960s and 1970s that the states and Congress passed legislation intended to protect children with disabilities right to a free and appropriate public education (Yell et al. 1998). Unfortunately, many children with disabilities continued to receive none or inappropriate educational services after these legislative changes (Steedman 2007).

In an effort to better serve children with disabilities, the federal government enacted the Education for All Handicapped Children Act of 1975 (EAHCA; Yell et al. 1998). This act was designed to provide all children with disabilities more extensive educational rights. In 1990, this act was amended and renamed the Individuals with Disabilities Education Act (IDEA). IDEA continues to undergo revisions designed to better protect these rights and facilitate the success of children with disabilities. It was most recently amended in 2004, with final regulations published in 2006 and 2011 (US Department of Education

2017). IDEA 2004 promises all children an appropriate education, but there continues to be debate concerning the extent and quality of services that schools are required to supply. Further, many schools report that they lack the funds and resources required to provide students with appropriate services (Block and Block 2007; please see the section “[Current Knowledge](#)” for more information).

Several Supreme Court cases have also been instrumental in further clarifying and adapting elements of IDEA 2004. One Supreme Court ruling in particular, *Winkelman v. Panama School District* (2007), has been identified as one of the most important Supreme Court rulings impacting the United States’ special education system (Yell et al. 2009). In their ruling of this case, the Supreme Court expanded the definition of free and appropriate public education (FAPE) under the IDEA 2004 to allow parents the right to be involved in all aspects of their child’s education, including the IEP process (Yell et al. 2009).

Current Knowledge

The Individuals with Disabilities Education Act (IDEA) of 2004 requires school districts to provide eligible individuals with ASD and other disabilities ages 3–21 with a free and appropriate education. This education should be designed around the students’ individual strengths and deficits. Each student’s program should include the special education and other services the student needs to make progress and should be delivered in the least restrictive environment possible. The program should target the skills that the student needs to achieve independent functioning, continue his or her education, and succeed in the workforce. Each of these main components is briefly described below.

Individualized and appropriate education. Although children with ASD share common areas of deficit, there is considerable variation in individual students’ abilities and impairments. Because of this heterogeneity, no single educational program will benefit all students with

ASD. IDEA recognizes this and requires that each student receive an education designed to build upon his or her strengths and address his or her deficits. Each student’s educational program must be detailed in an individual education plan (IEP). This plan should be developed by a multidisciplinary team including school personnel, relevant professionals (e.g., an ASD specialist, speech and language pathologist, or occupational therapist), and the student’s parents. The IEP should describe the student’s current abilities, his or her goals for the next year, and the specific services and accommodations that the child will receive to facilitate his or her progress. The IEP team must meet to review and update the IEP at least once a year. Parents or school staff can request additional IEP meetings any time that they feel the plan is not meeting the student’s needs.

Special education and other services. IDEA requires that eligible students with ASD receive the special education and related services that they need to benefit from their educational program. Special education refers to any curricular or instructional modifications that the child needs to progress. Related services refer to any additional support that will help the child to succeed. For children with ASD, speech therapy, occupational therapy, and transportation to and from school are common related services (Steedman 2007). When developing these special education and other services, the schools are required to use evidence-based practices (Odom et al. 2010). In other words, the school should use instructional practices or interventions that have received empirical support. Using educational strategies that have been found to benefit at least some children with ASD is believed to increase the likelihood that this intervention will benefit the current student with ASD (Morris and Mather 2008). Considerable debate remains over the extent and quality of services that schools are required to provide. The Supreme Court ruled that schools may not deny a child services based on the cost. However, the Supreme Court has also declared that schools do not have to offer children with disabilities the *best* education possible. Instead, services must allow children to “benefit” from their education (Steedman 2007).

In addition, the State Education Agencies' definition and corresponding evaluation of ASD has become problematic in recent years (Pennington et al. 2014). These definitions have differed by state, impacting which individuals qualify for special education and other services. Pennington et al. (2014) suggests that state and federal policy changes should be made to improve the definition of and the evaluation procedures used to assess ASD as an educational disability.

Least restrictive environment. IDEA states that each student's educational program should be implemented in the least restrictive environment possible (Alquraini 2011). Whenever possible, the student's special education and other services should be delivered in general education classrooms with typically developing peers. However, the IEP team must determine which type of placement best facilitates the academic, social, and behavioral progress of the student. Placement options include inclusion, special education, and mainstreaming. Inclusion is the least restrictive environment possible. Inclusion is generally defined as placement in a general education classroom with neurotypical peers, while providing additional services as needed (Alquraini 2013). These services can be provided within the general education classroom (i.e., push-in services) or outside of the classroom (i.e., pull-out services). Advocates of inclusion argue that this environment provides students with ASD more rigorous academic instruction and increased access to appropriate peer models and interactions. However, others contend that general education classrooms do not meet the special learning needs of students with ASD. Placement in a special education classroom is considered a more restrictive environment. Special education classrooms are populated by students with disabilities. They tend to contain fewer students and have a higher adult to child ratio. Teachers typically tailor their instruction to the special needs of their students. These classrooms may provide a more supportive environment for the students, but are often believed to be less academically rigorous and provide fewer opportunities for typical peer models and interactions. Students with ASD may also be mainstreamed, spending part of their day

in a special education classroom and part of their day in a general education classroom (Mesibov and Shea 1996). This placement allows children to receive more individualized special education instruction while also exposing them to typical curricula and peer models. However, the desired benefits to simply exposing children with ASD to neurotypical peers is unclear.

Program Quality Indicators

As previously noted, it is not possible to develop a single "best" program for students with ASD. However, researchers and professionals have used existing research and their professional experience to develop a number of program quality indicators or components of effective programs. Several of these components are described below; however, this list is not exhaustive. For full lists and comprehensive descriptions of program quality indicators, please see Colorado's Autism Program Quality Indicators (Colorado Department of Education 2016) and the cited references. The National Autism Center (2009, 2015) also provides information on the quality of ASD programs currently being implemented in schools.

Child assessment. Assessments allow educators to identify the strengths and deficits of children with ASD. Assessments should be comprehensive, with measures of the child's social and language skills, academic skills, adaptive and maladaptive behaviors, and cognitive abilities across settings. The selected assessments should provide information that can be used to inform the student's educational program (Crimmins et al. 2001).

Individualized education programs. The IEP should state the student's current level of functioning across communicative, social, academic, and developmental domains in school, home, and community settings. This information should be used to formulate new, measurable goals that will facilitate the child's success and independence across skill domains and environments. The IEP should specify the special education and related services that will be used to promote student progress (Steedman 2007). These may include parent services or training that will help the parents facilitate child progress in home and community

settings. These services and accommodations should be detailed so that all parties (e.g., parents, school staff) understand their roles and responsibilities (New Jersey State Department of Education 2004). For added clarity, Ruble et al. (2010) developed an evaluation tool to assess whether IEP's are consistent with the requirements put forth by IDEA and the National Research Council for children with ASD.

Progress monitoring. Effective programs should include ongoing and systematic measurement of individual student progress towards set IEP goals. The information gained from progress monitoring should be used to make appropriate educational decisions. When a student meets a set goal, the educational team should develop new goals to further facilitate child progress. When a student does not progress towards meeting a goal, the educational team should consider adjusting the method or intensity of the student's current program to better meet his or her needs (Crimmins et al. 2001; New Jersey State Department of Education 2004). Precision teaching is one approach to measuring a student's progress (Please see the ► [“Precision Teaching”](#) chapter for more information).

Curriculum. Each student's educational program should focus on the skills that he or she needs to achieve independent functioning, continue his or her education, and succeed in the workforce. Therefore, educational programs should address a wide range of skills, including communication and social skills, adaptive skills, academic skills, and, for older students, vocational skills (Please see the ► [“Curriculum”](#) chapter for more information). The specific content of each student's educational program should be based on his or her current functioning level and be adjusted as needed. Whenever appropriate, the curriculum should integrate age-appropriate state standards (New Jersey State Department of Education 2004; Noland et al. 2007).

Instructional methods and activities. Whenever possible, instructional methods and activities should be research-based. Methods and activities should be adapted to the strengths of the child with ASD. Skills should be targeted within appropriate instructional formats (e.g., individual,

small-group, or large-group instruction). When appropriate, skills should be targeted via naturally occurring opportunities and reinforcers. Programs should include components designed to promote independent skill use, generalization across people and settings, and maintenance (Crimmins et al. 2001; New Jersey State Department of Education 2004).

Challenging behaviors. Children with ASD often demonstrate stereotypic, disruptive, or self-injurious behaviors (Lopez et al. 2007). Programs should have a process for systematically assessing the function of these behaviors (e.g., functional assessments). This information should be used to develop a plan to eliminate the challenging behaviors and replace them with more adaptive behaviors (Crimmins et al. 2001; New Jersey State Department of Education 2004). A focus in recent years has involved implementing more positive behavioral interventions and services (PBIS) in schools, in an effort to reduce students' challenging behaviors (Kauffman 2015).

School personnel. School staff (e.g., teachers, other service providers, paraprofessionals) should be educated on the needs and strengths of students with ASD, effective educational practices, methods of individualizing educational programs to meet each student's needs, and behavior management and naturalistic teaching strategies. All staff should attend professional development workshops. Paraprofessionals, who tend to have less knowledge and experience, should receive continuous supervision and instruction from classroom teachers and other personnel. The program should have enough personnel (teachers, aides, therapists, etc.) to meet the needs of the students. Personnel should be familiar with each student's IEP and be aware of their role in its implementation (Crimmins et al. 2001; New Jersey State Department of Education 2004; Noland et al. 2007).

Family involvement. Legally, schools are required to include parents in the development of the student's educational program (Yell et al. 2009). Involving parents and family members in the development, implementation, and revision of the student's program is believed to increase program effectiveness. Therefore, the school should

make an effort to inform or refer parents to information on available services and their student's program and progress. Parents should also be given support and training that allows them to better meet their student's needs in home and community settings. Student's programs should be developed with consideration of the family's beliefs and values (Crimmins et al. 2001; New Jersey State Department of Education 2004).

Sample Schedule and Activities

A sample special education classroom schedule, activity descriptions, and recommendations are provided below. The activities can be adjusted to meet the individual needs of each student.

Consulting activity schedules. Activity schedules are a great way to prepare the student for the day's activities and transitions and to increase independence (Koyama and Wang 2011). Using visual activity schedules with students on the spectrum is considered an evidence-based practice (Knight et al. 2015). Each classroom should have a clearly visible general schedule, and each student should have an individual schedule detailing his or her specific activities for the day. Depending on the student's level of functioning, a schedule could be a written list or involve pictures.

Opening circle. Opening circle is a good time to target communication skills and attending in a large-group setting. Opening circle activities may include calendar time, singing songs, or sharing about a given topic (e.g., what students did over the weekend or favorite ice cream flavor). This type of activity can be implemented with young children with ASD during the preschool and elementary school years. It is not commonly implemented in middle or high school settings.

Individual work time. Individual work time should focus on each student's IEP goals. The following steps should be taken to maximize on-task behavior and correct responding.

- Structuring the work environment. Individuals with ASD benefit from a structured work environment (Bennett et al. 2011). Structuring the

work environment may include a work area with minimal distractions, clearly presenting the demand, visual instructions, and immediately reinforcing a correct response with praise, tokens, or tangible reinforcers (Ganz 2007).

- Brief stimulus assessment task. To ensure that each student is motivated, a brief stimulus assessment should be conducted at the beginning of each work session to identify items that can be used as reinforcers. In a brief stimulus assessment task, students are presented with a number of potential reinforcers, and the first items they choose are considered the preferred items. These items should then be used during the following work session (Paramore and Higbee 2005).
- Varying maintenance and acquisition tasks. During individual work time, the one-to-one aide should present the student with a mix of maintenance and acquisition tasks (Benavides and Poulson 2009; Charlop et al. 1992). For example, if a student is learning expressive language and categories but has already mastered receptive body parts, a work session should include trials on all three tasks.
- Using an appropriate level of prompting. As students acquire a given task, they will need different levels of prompting or support. Teachers and aides should give the student the minimal prompt necessary to help them succeed at the given task.
- Using a variety of preferred reinforcers. To make sure that the student stays motivated and does not grow bored with their reinforcer, the student should be reinforced with different preferred items throughout the session (Milo et al. 2010; Polín and Pérez 2017).
- Incorporating naturalistic teaching opportunities. The classroom provides a number of opportunities for naturalistic teaching strategies, such as incidental learning. Preferred toys may be placed on high shelves or in clear, hard to open bins so that the student must ask for them. Using naturalistic teaching strategies in the classroom promotes generalization and spontaneous use (Charlop 2017).

Lunch time. Meals are ideal times to provide natural learning opportunities. For example, instead of automatically providing a student with his or her food, the teacher or aide may wait for the student to request that the food be passed to them.

Small-group time. Small-group time is the perfect time to practice communication and social skills in a fun, motivating environment. Teachers or classroom aides can facilitate peer interactions during a variety of desired activities. These activities may include board or card games, arts and crafts, or conversations about preferred topics.

Physical education/outside play. Physical activity has been shown to decrease stereotypic behavior in individuals with ASD (Petrus et al. 2008). There is also research evidence supporting the assertion that for this population, exercise can help increase on-task behavior during subsequent academic instruction (Mahar et al. 2006). In addition, having students with ASD participate in small-group or team games provides opportunities to facilitate communicative and social interactions. During outside play, students may participate in activities such as kickball, tag, or relay races (Miltenberger and Charlop 2014).

Closing circle. Closing circle is a good time to practice communication skills and attending in a large-group setting. Closing circle activities may include reviewing the day's activities, asking students to share their favorite part of the day, or having students share a favorite item from home with the rest of the group.

Token systems. Tokens can be used to reinforce correct responding and appropriate behavior throughout the day (Tarbox et al. 2006). Using objects of obsession (e.g., a favorite TV character) as the tokens may be especially effective (Carnett et al. 2014; Charlop-Christy and Haymes 1998). At the end of the day, students should be given the opportunity to spend any tokens they have earned on preferred items. If students choose, they should be allowed to save their tokens until they have earned enough for a bigger item.

Future Directions

Over the past several decades, there have been tremendous gains in the education of students with ASD (Parsons et al. 2011; Yell et al. 2009). However, the education of children with ASD is far from perfect. While IDEA guarantees children with ASD and other disabilities an appropriate education, its implementation is often less than ideal (Block and Block 2007; Pennington et al. 2014). Schools report that they lack the funds and resources required to meet the extensive and diverse needs of the increasingly large population of students with ASD and other disabilities (Block and Block 2007). In addition, some students in need of these services may not qualify for them because of the vagueness of the State Education Agencies' definitions of ASD and the variability with how it is evaluated in different states (Pennington et al. 2014).

Two ways to address these issues are to provide research to develop the highest quality definition of and evaluation procedures used to assess ASD as an educational disability in schools and to continue to research effective educational practices for children with ASD. IDEA recognizes the importance of research-based practices (Steedman 2007), but the necessary body of research is yet to develop. Although many strategies have been shown to be effective when working with children with ASD in tightly controlled settings, much less is known about the outcomes of these strategies when implemented at school. There is a particular need for research addressing effective educational interventions for older and more impaired students with ASD (Noland et al. 2007). Researching interventions and identifying effective practices will provide educational teams with information that can be used to develop efficient and effective educational programs (Morris and Mather 2008).

Educational Interventions

Michelle Lestrud
The Gengras Center, University of Saint Joseph,
West Hartford, CT, USA

Definition

The role of education for all children is to provide the experiences needed to learn skills that will lead to “personal independence and social responsibility” (National Research Council [NRC], 2001, p. 40). Educational interventions provide students with the support needed to acquire the skills being taught by the educational system and

should address functional skills, academic, cognitive, behavioral, and social skills that directly affect the child's ability access an education. For students with autism spectrum disorders, the interventions often address some of the core deficits in the areas of communication, social skills, and behavioral differences. The interventions should be aimed at skills that need to be acquired or that need to be performed more often to lead to successful results. For children with autism, these educational interventions must be specific and targeted to address the deficits and lead to generalization and maintenance.

Educational interventions vary widely depending on the needs and age of the student, resources available, background of the team members, philosophy of the program, parental requests and beliefs, and student progress. In addition, the interventions used are based on the child's profile which should include thorough assessments and reports detailing strengths, weaknesses, learning style, preferences, past successes, etc., and should lead to the most successful outcome. Data to monitor and assess the interventions should be reviewed a regular basis to determine effectiveness and to link progress or lack of progress specifically to the intervention. Prescribed interventions change over time as new research is conducted, as new theories are developed, and as new technology is designed.

Educational Psychology

Arlette Cassidy

The Gengras Center, University of Saint Joseph,
West Hartford, CT, USA

Definition

Educational psychology is the study of the relationship between learning and our physical and social environments. Educational psychologists study the psychological processes involved in learning and develop strategies for enhancing the learning process. Educational development focuses on the cognitive development, and what a teacher can do impacts the development of the child. It teaches about how children learn and how they can be taught for them to be successful. Educational psychologists “study what people think and do as they teach and learn a particular curriculum in a particular environment where education and training are intended to take place.” Two fundamental assumptions that underlie formal educational systems are that students (a) retain knowledge and skills they acquire in school and (b) can apply them in situations

outside the classroom. Aspirations of the discipline rested on the application of the scientific methods of observation and experimentation to educational questions. Ultimately, the goal of those working in the field of educational psychology is to understand the processes and conditions under which human beings, both in childhood and throughout their lifespan, learn to become mature human beings who fulfill their individual potential, live in service to their community, and exercise loving stewardship over the environment.

It is likely that educational psychologists will continue to contribute to education as they learn more about the brain and how learning occurs; the development of intellect, affect, personality, character, and motivation; ways of assessing learning; and the creation of multifaceted learning environments.

The *Journal of Educational Psychology* is a peer-reviewed academic journal that was established in 1910 and covers educational psychology. It is published by the American Psychological Association.

Synonyms

[Academic testing](#); [Achievement testing](#)

Definition

Educational testing refers to the formal assessment of academic achievement. This can take the form of group or individually administered tests which to formally evaluate performance in the areas of reading, decoding, and comprehension; writing, spelling, mathematics, computation, and problem solving; and, on occasion, other subject areas such as science. Test scores compare the individual's performance to age-based or grade-based normative groups. These scores are frequently used as part of the assessment academic progress and in the diagnosis and monitoring of specific learning disabilities or learning disorders. Commonly used individually administered educational testing instruments include the Wechsler Individual Achievement Test 3rd Edition, the Woodcock-Johnson Achievement Battery, and the Kaufman Achievement Battery for Children Edition II.

Educational Therapy

Rita Jordan

School of Education, University of Birmingham,
Edgbaston, Birmingham, UK

Synonyms

[Education as therapy](#); [Educational psychotherapy](#);
[Therapeutic education](#)

Definition

Educational therapy (also known as educational psychotherapy) has roots in early psychoanalytical models of child development but is now more concerned with remediation of learning and emotional difficulties based on neuropsychological models. In the UK, there is a master's qualification in educational psychotherapy but no official role for educational therapists (ETs) within the educational system and most work is undertaken privately. In the USA, the work of ETs is also private but certified by professional organizations such as the Association of Educational Therapists (AET). The focus of the work of ETs is on those with specific learning difficulties (such as dyslexia) and emotional and behavioral difficulties, rather than ASD. Their goal is to improve academic success (Ficksman and Adelizzi 2010) by addressing psychological factors that may be impeding learning. The AET approves training courses in educational therapy, which are at postgraduate to master's level. Entry requirements include qualified teacher status, educational psychology, or qualified therapist status with some experience of special education. Other routes may be approved by the AET. ETs may work with individuals within the autism spectrum, but the efficacy of such work has not been established. They focus on changing, or building, underlying psychological processes which are involved in auditory processing, reading, or on positively influencing self-esteem and optimism, which are known to be related to academic success. Evidence of efficacy, even in cases without an ASD, is largely based on case study or

pre-post designs (Maslow and Ungerleider 2007), which are not scientifically robust.

Jordan (2005) used the term “educational therapy” to refer to aspects of special education in autism spectrum disorders (ASD) that address the core symptoms; it is included as a concept in specialist autism training for professionals in the UK and features in the UK and European guidelines for good practice in ASD. It is intended to be an adjunct to academic education, but individuals with ASD will also need compensatory techniques to help them access the culturally valued skills, knowledge, and understanding to which everyone is entitled (i.e., the usual curriculum). Educational therapy is intended to characterize the work of all who educate and care for those on the spectrum; it is not confined to therapists. It is based on the recognition that explicit specialist education can help remediate many problems in ASD, but specific attempts to do so require evaluation. Golan et al. (2010) (a matched controlled study without random allocation to groups) and Herrera et al. (2008) (a small case study) are typical of evaluations in this area, where there is still need for more robust scientific evaluation.

Neither “education as therapy,” as used by Jordan, nor the work of ETs is meant to replace the entitlement of children with ASD to a full and broad education. Therapists, including ETs, may have a role in ASD in addressing specific difficulties or in meeting emotional and mental health needs. ETs may also address some of the comorbid specific learning difficulties that may accompany ASD. However, such roles are aids to development and to access educational entitlement, rather than alternatives to education. Likewise, Jordan's view of educational therapy expresses the need to extend education in ASD to include specific teaching of aspects of development that occur naturally in those not on the autism spectrum, not to limit education to those aspects.

EEG Abnormalities as a Biomarker of Severity in ASD

Antonio Gennaro Nicotera
Oasi Research Institute – IRCCS, Troina, Italy
Child Neuropsychiatry Unit, Department of
Human Pathology of the Adult and
Developmental Age, University Hospital
“G. Martino”, Messina, Italy

Synonyms

EEG anomalies; EEG discharges; Epileptiform abnormalities

Definition

Compared with the healthy population, patients with autism spectrum disorder (ASD) have an increased incidence of epilepsy (2–3% vs. 5–46%, respectively). Studies show a higher risk of autism in patients suffering from specific forms of epilepsy such as infantile spasms and Lennox-Gastaut syndrome. EEG abnormalities in subjects with ASD, without epilepsy, are detected with prevalence ranging from 6.7% to

61% and associated with more severe behavioral problems, thus indicating a distinct neuroelectrophysiological signature. The EEG findings include non-epileptiform abnormalities, such as slow activities or asymmetries in background rhythm, and, more frequently, epileptiform abnormalities. Commonly, the epileptiform abnormalities are morphologically classified as follows: spikes or sharp waves, slow waves, generalized wave-spike, or generalized polyspikes. Also, epileptiform abnormalities include interictal discharges (generalized, multifocal or focal, unilateral or bilateral), affecting different brain areas. Although there is no consensus among researchers, it seems that the EEG abnormalities occur more frequently in temporal regions in ASD population. The EEG abnormalities are most commonly encountered during sleep recording, suggesting the importance of performing the EEG in siesta status and prolonging the EEG recording in order to grasp all the sleep phases in management of ASD patients. Several studies reported a significantly higher incidence of epileptiform abnormalities in patients with ASD when compared with subjects with Asperger, highlighting that the increasing severity of autistic symptoms might be associated with higher likelihood of epileptiform abnormalities. In particular, EEG abnormalities in children with ASD were correlated with a higher incidence of autism severity, hyperactivity, anger outbursts, aggression, negative or destructive behavior, motor stereotypies, intellectual disability, language impairment, and self-harm. Whereas the association between epilepsy and cognitive disability is well-known, the potential role of isolated EEG abnormalities on cognitive functioning in subjects with ASD is uncertain. A well-known example of how EEG abnormalities can be associated with speech disorders is Landau-Kleffner's syndrome, an acquired epileptic aphasia in which bilateral and independent continuous sleep waves, predominant on temporal lobes, are associated with severe language deficits and, often, regressive behaviors. Rolandic epilepsy has been also associated with cognitive impairment, particularly in the presence of frequent epileptic discharges. In this type of epilepsy, written and oral language deficits are also documented. These data suggest that EEG

abnormalities could be considered as a neurophysiological biomarker of severity of cognitive and behavioral problems associated with ASD. However, whether the epileptiform abnormalities are considered as an expression of an underlying brain dysfunction, how these functional abnormalities are related to the clinical phenotype is still unclear. The literature data highlighting a clear association between epileptiform abnormalities and language disorders, hyperactivity, and intellectual disability in subjects with ASD are in line with a modern interpretation of neurodevelopment disorders, considered as a continuum of disease rather than distinct nosological categories. In fact, the presence of EEG abnormalities in different disorders, both in autistic and non-autistic subjects, suggests that structural and/or functional alterations of the cortex could be considered as a common thread among different pathologies. Therefore, the presence of EEG abnormalities in subjects with ASD could be useful for a more correct selection of patients for gene sequencing studies and in the identification of patients that may have a better outcome on anti-convulsants. Although “treating the EEG” is based on the hypothesis that discharges may contribute to the behavioral, language, or cognitive disturbances, to date, there are only few favorable case reports of EEG treatment in patients with ASD. Specifically, the literature suggests that only a small proportion of ASD population with EEG abnormalities improve with antiepileptic drug treatment. In conclusion, epileptiform abnormalities, even in the absence of epilepsy, are common in subjects with ASD and correlate with the severity of cognitive and behavioral problems associated with ASD. Therefore, it is reasonable to look at EEG abnormalities as a neurophysiological biomarker of ASD severity.

EEG Connectivity During Social Engagement in Autism

Mark Jaime

Division of Science, Indiana University-Purdue University, Columbus, Columbus, IN, USA

Definition

The magnitude of coupling between two distinct electroencephalogram (EEG) signals measured during social engagement in individuals with autism.

Historical Background

Several theories of autism spectrum disorder (ASD) propose that a disturbance in neural organization during early development results in altered brain connectivity and trajectories of impaired social and communicative development (e.g., Belmonte et al. 2004; Courchesne and Pierce 2005; Just et al. 2004, 2007). Altered brain connectivity in ASD has been posited to result from excessive brain growth and aberrant neural pruning during early neurodevelopment (Courchesne and Pierce 2005). Theoretically, this can have consequences for the developing *social brain* – a functional network of brain structures that are involved in mediating social functioning (Adolphs 2009). For example, altered brain connectivity can result in inefficient integration among neural networks that support social cognitive function. Children with ASD may therefore develop with limited neurocognitive resources to effectively deal with the information processing demands of a dynamic social world. This may in turn degrade the affected child's social experiences during critical periods of experience-dependent neurodevelopment, thereby exacerbating social deficits. Thus, altered brain connectivity – particularly in the social brain – may be a potential nexus of social impairment in ASD.

However, characterizing an exact connectivity pattern that is specific to all of the dynamic brains of individuals with ASD is unlikely. This is evidenced by a large brain connectivity literature in ASD that presents mixed findings indicating reduced functional connectivity at rest and during a variety of tasks (e.g., Cherkassky et al. 2006; Coben et al. 2008; Darmala et al. 2010; Jones et al. 2010; Just et al. 2004, 2007; Kana et al. 2006; Koshino et al. 2005, 2008; Lazarev et al. 2013; Lynch et al. 2013; Villalobos et al. 2005; Wicker et al. 2008) as well as evidence of increased resting and task-based functional connectivity in ASD (e.g., Lynch et al. 2013; Shih et al. 2010; Uddin et al. 2013a). There are also findings in which both increased and decreased functional connectivity is observed in individuals with ASD depending on the frequency of neural

oscillations and distance between neural networks (e.g., Kitzbichler et al. 2015). Other factors that make delineating functional connectivity in ASD difficult are the use of different tasks, age groups, and measurement techniques (e.g., Kana et al. 2014; Uddin et al. 2013b).

Current Knowledge

The measurement of brain connectivity involving electroencephalography (EEG connectivity) is derived from biophysical processes in the brain that differ from the biophysical processes used in other neuroimaging approaches. Brain connectivity measures derived from functional magnetic resonance imaging (fMRI), for example, use the hemodynamic response – the rapid blood flow to active neuronal populations – to examine coupled activity between defined regions in the brain. EEG connectivity measures use oscillating electrical activity captured by sensors on the scalp (Nunez and Srinivasan 2006). These electrical fields on the scalp's surface are generated from the synchronous synaptic activity of millions of cortical neurons. They are represented in the EEG as oscillating waveforms that fluctuate in frequency and amplitude over time. The human EEG typically fluctuates in amplitude between 10 and 100 microvolts and between 1 and 100 Hz in frequency. Furthermore, EEG frequencies are clustered into *bands* that have been associated with different brain states and/or mental activities. For example, medium to high frequency bands are associated with attention, perception, and cognitive processing and lower frequency bands with a relaxed state or deep sleep. The EEG frequency bands are as follows: 1–4 Hz (delta), 4–7.5 Hz (theta), 8–12 Hz (alpha), 12.5–30 Hz (beta), and 30–100 Hz (gamma). EEG connectivity metrics can measure coupled activity both within and between frequency bands (Cohen 2014).

The use of EEG connectivity measures has advantages and disadvantages relative to fMRI. For example, EEG connectivity measures have better temporal resolution. That is, because the time course of electrical potentials in the brain is faster (in the order of milliseconds) than the

hemodynamic response, EEG connectivity measures are presumed to be more closely linked to perceptual and cognitive processes. Another advantage is that EEG acquisition does not require the participants to be placed inside a magnetic scanner; therefore, EEG can be more readily acquired in children and infants. One disadvantage of EEG connectivity is that it cannot inform about connectivity between specific brain structures. This poor spatial resolution of EEG connectivity occurs because the electric fields produced from neural generators within the brain instantly spread through biological tissue as they move up toward the sensors on the scalp, a process referred to as volume conduction (Nunez and Srinivasan 2006). As a result, coupled activity between two EEG sensors can reflect activity from a single rather than distinct neural generators. Volume conduction can therefore lead to spurious EEG connectivity results and is a confound that can plague studies involving EEG connectivity. There are however a number of computational approaches that can mitigate – but not completely remove – the effects of volume conduction in EEG connectivity research (Cohen 2014). In addition, the use of advanced quantitative methods and high-density EEG nets (100 + sensors) can be used to localize sources in the brain where the neural signal is generated (Michel and He 2019). One commonly used EEG connectivity metric is *coherence*. Coherence is a statistical estimate of the amount of phase stability between two EEG signals and represents the degree of synchronous activity between distinct neural networks in the brain (Nunez and Srinivasan 2006). Since coherence reflects that stability of phase differences between two EEG oscillating signals, the use of the coherence metric can reduce the volume conduction confound (Bastos and Schoffelen 2016).

Despite a large number of EEG connectivity studies in children and adults with ASD during rest, sleep, and the performance of nonsocial tasks, relatively few ASD studies have examined EEG connectivity during tasks involving social engagement (see O'Reilly et al. 2017; Schwartz et al. 2017 for a review on EEG connectivity studies in ASD). Given that one of the core

deficits of ASD is social functioning, there is knowledge to be gained from EEG connectivity studies that examine the ASD-affected brain while engaged within a social context. Prior fMRI research has explored the socially engaged brain in ASD by scanning subjects during live person-to-person social interaction via linked video feeds. This work has demonstrated that adults with ASD have reduced activity in brain areas that support social cognition relative to non-ASD controls (Redcay et al. 2013). However, a potential issue with fMRI work is that participants must remain still as movements can distort the signal and affect the interpretation of the results. These movement constraints can create conditions that may feel too artificial as well as present methodological difficulties when implemented with children with ASD.

Studies that have examined EEG connectivity during social engagement thus far have mainly involved participants passively observing social stimuli such as still images of faces or videos engendering joint social attention. Consistent with the broader literature on functional connectivity in ASD, EEG connectivity studies during social engagement report variable results such as reduced and/or increased coherence across different frequency bands, between sensors located on the left and right side of the head (interhemispheric coherence), and between sensors located within the same side of the head (intra-hemispheric coherence). For example, in a study that examined coherence during the perception of static faces in infants who later received a diagnosis of ASD, there was increased left intra-hemispheric coherence in the faster gamma frequency band (Keehn et al. 2015). Another study examined coherence in infants who had an older sibling with ASD (at-risk infants) as they observed social videos of a woman playing the game “peek-a-boo” (Orekhova et al. 2014). In this study, the at-risk infant group demonstrated increased interhemispheric coherence between frontal sites in the alpha frequency band relative to low-risk infants. Recently, Haartsen et al. (2019) demonstrated that alpha band EEG connectivity in 14-month-old infants who later met

ASD criteria at 36 months was positively associated with the severity of restricted and repetitive behaviors as measured by the Autism Diagnostic Observation Schedule (ADOS-2; Gotham et al. 2007). Taken together, this pattern of results suggests that infants who are more likely to display symptoms of ASD in later development may initially have overconnected brains.

Altered EEG connectivity during social engagement has also been reported in children already diagnosed with ASD. Carson et al. (2014) measured coherence while children watched videos of either a familiar or unfamiliar person reading a story. They also measured coherence during a rest condition. Results revealed that across both story conditions, there was decreased interhemispheric coherence in the alpha band in children with ASD relative to the typically developing (control) group. However, there was decreased alpha coherence in the rest condition as well. Jaime et al. (2016) examined coherence in adolescent children with ASD while they observed a series of 30-second videos that engendered joint attention. Joint attention involves the coordination of visual attention to share a point of view with another person and is recognized as one of the central impairments in early nonverbal social communication in ASD (Mundy 2016). These joint attention videos consisted of a red dot appearing at one of the four corners of the screen. As the red dot appeared in each corner, a person positioned in the center of the screen subsequently gazed (with the eyes and head) at one of the corners. In the congruent condition, the person gazed at the corner in which the red dot appeared. In the incongruent condition, the model gazed away from the corner in which the red dot appeared. The congruency of the joint attention videos was manipulated because prior research has demonstrated that when adult participants observe inconsistencies between the direction of gaze and a target, the superior temporal sulcus (STS) – a brain structure associated with social cognition – shows an increase in activity in typically developing adults but not in adults with ASD (Pelphrey et al. 2005). Thus, Jaime et al. (2016) hypothesized that the incongruent joint attention

condition would result in an increase in coherence for typically developing adolescents but adolescents with ASD would not show a change in coherence in response to the incongruency of joint attention.

The Jaime et al. (2016) study reported that the ASD group had reduced coherence in the alpha frequency band between the right temporal and central (i.e., midline of the scalp) EEG sensors. These are sensors that are located topographically near the STS region. There was reduced temporal–central alpha coherence only when coherence was collapsed across congruent and incongruent joint attention conditions and a separate condition in which adolescents fixated to a static dot. Thus, inconsistent with Pelphrey et al. (2005), the effect of incongruency did not appear to affect functional EEG coherence in either diagnostic group. The authors speculated that the instructions provided to participants, which was to “follow the dot,” may have precluded participants from inferring the actor’s intentions during the incongruent condition because participants were likely focused on performing the task correctly. Thus, a procedure in which participants would be allowed to visually explore the joint attention videos freely and without instruction might have revealed an interaction between congruent and incongruent joint attention and diagnostic status. The authors also reported that right temporal–central alpha coherence during the congruent and incongruent joint attention conditions correlated positively with performance on a test of social cognition in typically developing adolescents, but not in adolescents with ASD. Finally, two studies have examined EEG connectivity during social engagement in samples with high-functioning adults with ASD. Catarino et al. (2013) reported reduced interhemispheric alpha coherence in the ASD group relative to typically developing controls during a task requiring face recognition. However, these diagnostic group differences were only observed between one pair of temporal EEG sensors. Another study with high-functioning adults with ASD examined phase coupling across frequency bands during a task involving the identification of emotional

expressions in photographs of faces (Tseng et al. 2015). Results revealed reduced delta–theta phase coupling in the ASD group between central and parietal EEG sensors.

Due to the limited number of studies and variability in methodology, it is difficult to delineate the nature of functional connectivity during social engagement in individuals diagnosed with ASD. Thus far these studies do reveal a trend of reduced alpha band EEG connectivity both within and between hemispheres during social engagement tasks in children and adults with ASD. However, more research is needed, particularly studies that use standardized social interaction tasks such as the ADOS-2 in order to better characterize the nature of functional connectivity in the socially engaged brains of individuals with ASD.

Future Directions

Efforts to identify early biomarkers of ASD remain a key clinical goal for improvements in diagnosis. One research area that is garnering attention, but is still in its infancy, is the merging of advanced computational, data-driven techniques with EEG for the objective detection of ASD. There is a rapidly growing literature in the computer science field indicating that artificial learning systems can be powerful tools for detecting idiosyncrasies in the spectral patterns of EEG and can therefore be trained to accurately classify EEG records that indicate ASD from those that do not. There are recent findings that are in line with this hypothesis (e.g., Bosi et al. 2018), and data is rapidly emerging suggesting that machine learning algorithms that use EEG connectivity measures acquired during live social interaction in their feature set can achieve classification accuracies above 90% (Jayarathna et al. 2019). However, more studies with rigorous methodology and peer review will be needed for validation. If proven to be true, however, the integration of EEG connectivity during social engagement with machine learning approaches may significantly change the diagnostic process in the foreseeable future.

Definition

Postural control is the ability to keep an upright posture of the body within the base of support. Its purpose is to provide humans with stability and to orientate their bodies to perform a variety of tasks, such as standing, walking, and reaching (Horak 2006; Massion 1994). Postural control relies on a postural control system that is dependent on many aspects of the body (Horak 2006). All aspects of the body, such as the feet size, joint movements, and sensory processing within the brain, provide relevant information to the central nervous system for the

control of posture. The context of the surrounding also plays an important role in postural control. Information about the surrounding is picked up by the senses of vision, touch, and hearing and sent to the central nervous system. The central nervous system combines all of the information to make sense of the body position in the context of the surrounding. Any change in the surrounding can affect one's posture. Therefore, all information must be organized accurately so that the correct motor commands can be sent out to different parts of the body. The motor commands guide the body to move in the direction of front/back or left/right to keep the body in a stable posture (Winter 1995).

Postural control can be measured in several ways using standardized clinical tests or measuring instruments. It is mostly assessed while standing because standing is known to be inherently unstable (Hwang et al. 2016). Standardized clinical tests are usually used to assess postural control in clinics as they can be done in a short time (Mancini and Horak 2010). The tests help clinicians identify postural control problems in their patients and then use the information to guide treatments. Examples of these tests include the Peabody Developmental Motor Scales, Gross Motor Function Measure, Timed “Up and Go” test, and Berg Functional Balance Scale (Mancini and Horak 2010; Westcott et al. 1997). Instrumented measures of postural control are usually used to provide an objective assessment of postural control for research and sports (Mancini and Horak 2010). These instruments typically record ground reaction force exerted on the surface of the instruments when the person stands on it. The force signals are later quantified into the center of pressure measurements for further analysis. An example of these instruments includes the force platform (Mancini and Horak 2010; Paillard and Noe 2015).

Historical Background

People with autism spectrum disorder (ASD) have often been documented in research literature to have problems with postural control. A large

amount of research on postural control in ASD involves children with ASD. Using comparisons of postures between children with ASD and typically developing children, those with ASD have been shown to have unusual postures (Kohen-Raz et al. 1992). Unlike typically developing children, children with ASD tend to hyper-extend their backs and have low muscle tone and an unusual walking style (Paquet et al. 2016). Assessments of postural control using measuring instruments also show that children with ASD tend to have a less stable posture than typically developing children when there are changes in their surrounding (Kohen-Raz et al. 1992; Molloy et al. 2003). Overall, the research shows consistent findings of postural control problems in children with ASD.

Current Knowledge

While much is known about postural control in children with ASD, there is limited research evidence with regard to adults with ASD. Understanding postural control in both children and adults with ASD is essential to identify problem areas of postural control and to appreciate the postural control system and its development in those with ASD across the lifetime (Minschew et al. 2004). Over the past 15 years, only a small quantity of studies involving adults with ASD has been added to the literature (Lim et al. 2017). Therefore, little is known if postural instability in childhood ASD is normalized by adulthood.

Of the limited research about postural control in adults with ASD, there is poor consistency in the findings. Among the few studies, most of them examined if changes in visual information could affect postural control in adults with ASD. These usually involve participants opening and closing their eyes or looking at moving scenes while standing. Under these testing conditions, some studies have found that adults with ASD show similar control of posture as typically developed adults (Greffou et al. 2012; Travers et al. 2013). In contrast, other studies have reported a more unstable posture in those with ASD than

that in typical adults when they used visual information during postural control (Doumas et al. 2016; Morris et al. 2015). Two recent studies have also found that adults with ASD responded differently from typical adults in visual environments controlled by immersive virtual technology (Lim et al. 2018a, b). Adults with ASD showed a more unstable posture when they had to focus on a central target and when exposed to a busy, incoherent, and unfamiliar visual environment while standing (Lim et al. 2018a, b). In addition, adults with ASD appeared to invest a larger amount of attention in postural control than typical adults when visual information was used during postural control (Lim et al. 2018b). Although some of the studies have indicated an important influence of visual environment on postural control in ASD, further research is still needed to ascertain these findings.

There have been several proposed reasons for postural control problems in adults ASD. One reason concerns the aspect of sensory information organization in the central nervous system. Sensory processing problems are commonly reported in people with ASD outside of motor behavior (American Psychiatric Association 2015). Mechanisms that have been proposed to explain sensory problems in ASD include an increased excitation-to-inhibition ratio (Rubenstein and Merzenich 2003); increased endogenous noise (Simmons et al. 2009); and altered neural network connectivity (Markram and Markram 2010). Problems related to any of these mechanisms could result in a series of inaccurate information relayed within the system. Thus, this would diminish the capacity for generating appropriate motor commands for postural control. Additionally, problems with an inaccurate representation of the body in space as a result of any process would result in the delivery of inaccurate motor commands for postural control (Van de Cruys et al. 2014).

Problems with postural control could affect a person's independence, and thus further understanding of postural control in adults with ASD is essential. Problems with postural control could mean that adults with ASD face difficulty completing tasks that require a stable posture,

such as lifting and carrying items and overhead reaching. The ability to perform these tasks is necessary for adults who want to work and live on their own (Happé and Charlton 2012). In addition, older adults with ASD could face more problems with postural control due to age-related body changes. A combination of body changes related to old age and pre-existing postural control problems could reduce a person's capacity to complete tasks on their own and could increase the risk of fall in older adults with ASD (Happé and Charlton 2012). Besides the need to know more about postural control in adults with ASD, further understanding of postural control across people of different age groups in ASD is needed. Knowing how postural control develops with age could contribute to the advancement and development of diagnostic tools and treatments for people with ASD in all age groups.

Future Directions

There is scope for future research to expand the way postural control is assessed in adults with ASD. Postural control is influenced by different types of sensory information in the environment (Horak 2006). However, little is known about the impact of somatosensory and vestibular information on postural control in adults with ASD. An understanding of how different types of sensory information affect the control of posture would provide more insights into the postural control system in adults with ASD.

Future studies may also want to understand how the brain responds during a postural control task in adults with ASD. Currently, there is limited knowledge about the neural mechanisms responsible for postural control problems in ASD. Knowing how the brain responds during a postural control task could help to identify areas in the brain contributing to postural control problem in ASD.

There may be benefits to investigate the association between postural control and the level of functional independence in adults with ASD. Functional independence is important for people who work and live on their own. However, it

is unclear if and how postural control problems in adults with ASD affect their functional independence. Understanding the physical needs of adults with ASD could guide the planning of resources to help them cope with daily tasks at home and in the community.

It is also important for future research to involve people with ASD from different age groups. A comprehensive understanding of the postural control system in ASD relies on knowing how postural control is presented across all ages. This also includes people in age groups that are not commonly assessed in the research literature, such as adolescents and older adults with ASD. Findings from future studies that include people of different age groups will be useful to understand how the postural control system changes with age and to come up with ways to treat postural control problems in ASD.

Effectiveness of a SCERTS Intervention

Lu Yu and Xin Kang

Department of Applied Social Sciences, The Hong Kong Polytechnic University, Hung Hom, Hong Kong

Definition

The SCERTS (social communication, emotional regulation, and transactional support) model is an evidence-based multidisciplinary educational approach developed by a team of professionals trained in different disciplines (Prizant et al. 2003). The model focuses on addressing the core challenges faced by children with autism spectrum disorders (ASD) and their families by

enhancing competence in social communication, emotional regulation, and transactional support.

Historical Background

The SCERTS model was derived from abundant empirical research and clinical investigation into both conventional and unconventional social communication skills in ASD over two decades. Having recognized the core deficits of ASD in social interaction and emotional regulation, and the need for a comprehensive educational model that can address these impairments, a team of researchers and practitioners developed the SCERTS model. In developing this model, they made use of scholarly literature concerned with communication and with socioemotional development in children, as well as clinical experiences of ASD and other developmental disabilities. While SCERTS is intended to address common deficits in ASD, the model takes “into account critical individual differences across families in reference to their priorities, and their involvement in critical programmatic decision-making” (Prizant et al. 2003, p. 298). It can thus be implemented in an individualized manner and is considered family-centered.

The SCERTS model has two notable features. Firstly, the model focuses on social communication and emotional regulation, which resonate with the most important priorities in helping children with ASD to develop life skills (Handleman and Harris 2006; National Research Council [NRC, USA] 2001). Building competence in areas of socioemotional and communication skills in children with ASD helps them to achieve better long-term outcomes, and this model echoes the evidence-based practice recommended by researchers and practitioners working in the field of ASD and related developmental disabilities (Prizant et al. 2003). Secondly, the SCERTS model highlights the implementation of “transactional support” and the collective input by different social partners, which unites people surrounding the child to work together as a multidisciplinary team (O’Neill et al. 2010). Such a partnership among family, peers, teachers,

and professionals facilitates the implementation of individualized service in different settings, which helps children with ASD and their families to achieve more positive outcomes. The unique emphasis on multidisciplinary teamwork also makes the model flexible enough to incorporate other practices from approaches such as the Treatment and Education of Autistic and Communication Handicapped Children (TEACCH) (Schopler et al. 1995) and the Developmental, Individual-difference, and Relationship-based model (DIR) (Wieder and Greenspan 2005; Greenspan and Wieder 1997).

The SCERTS model provides a comprehensive framework that guides the development and implementation of different educational programs for children with ASD and for supporting families. It has been widely adopted in various intervention and education programs across the world (Molteni et al. 2013; Walworth 2007; Walworth et al. 2009). Researchers reported that programs based on the SCERTS model can have positive impacts not only for participating children with ASD but also for others involved, such as parents, special education teachers, and therapists (Prizant et al. 2003, 2005). Although the current research evidences vary in terms of methodology (e.g., randomized control trial, single-case experimental designs and case control, cross-sectional or longitudinal descriptive group research designs, etc.), they generally support the treatment impact in one or more domains focused on in the SCERTS model (Morgan et al. 2018; O’Neill et al. 2010; Walworth et al. 2009).

Current Knowledge

Evaluation study is a valuable tool for collecting, analyzing, and using information to answer basic questions about the effectiveness of intervention models, which helps researchers find out “what works” and “what does not work.” Limited evaluation studies have been conducted to systematically examine the effectiveness of the SCERTS model (Arick et al. 2003).

In the United Kingdom, researchers carried out a case study that investigated the impact of the

SCERTS model-based intervention on four elementary school students in a special education school. The results showed that, after 12 months of intervention, the participating students demonstrated significant improvement in the areas of joint attention, symbol use, mutual regulation, and self-regulation. The students also became more focused on tasks and ready to learn. Self-awareness of one's own needs and the use of regulations as required were also found to be improved in the four participants. It was further revealed that apart from the impact on children, the SCERTS model facilitated the development of positive multiagency cooperation in the school and supported collaboration among different school workers. The SCERTS model served as an effective way of working with children with ASD. This encouraged educators to think about their school curriculum and altered the culture of the school and the teaching style of adults (O'Neill et al. 2010).

Another reported case study was conducted in New Zealand. This examined the efficacy of a program that integrated the SCERTS model with music therapy for a 3-year-old boy with ASD. After 1 year of intervention, the boy showed positive changes in the areas of active learning, social membership, independence, cooperation, and appropriateness of behaviors (Ayson 2011). In the United States, researchers investigated the effectiveness of a SCERTS model-based parent-implemented intervention, the Early Social Interaction (ESI) Project, with 82 children diagnosed with ASD at 16–20 months (Wetherby et al. 2014). The intervention focused on teaching parents how to use strategies to support children's communication in everyday activities. Based on a randomized controlled trial (RCT), the effects of individual intervention (parents were trained at home or in the community) and group intervention (parents were trained in a clinic) were examined and compared in terms of participating children's social communication skills, adaptive behaviors, and developmental level. The results demonstrate the effectiveness of both individual and group intervention, while children in the individual home coaching group showed greater improvement on the social components of

communication, receptive language, and core social deficits. The researchers concluded that the SCERTS model-based parent-implemented intervention was effective, and little professional time was needed.

More recently, researchers reported a cluster randomized trial (CRT) that examined the effects of a SCERTS model-based intervention by classroom teachers in an elementary school setting in the United States (Morgan et al. 2018). A total of 60 elementary schools with 197 students with ASD and 129 teachers were randomly assigned to either a classroom SCERTS model-based intervention group or a normal school-based education group with autism training modules group. Standardized assessments, teachers' and parents' reports, and direct observation of student behaviors were employed to measure the intervention effect across various domains. Baseline and end-of-treatment assessments involved measures of active engagement (e.g., emotion regulation, productivity, social connectedness, directed communication, generative language production, and academic independence), adaptive behavior, executive functioning, and social outcomes. The results showed that the classroom SCERTS model-based intervention group had significantly better outcomes than the usual school-based education group with autism training modules group. Significantly better outcomes were found in the SCERTS group students' social participation, adaptive communication, social skills, problem behaviors, and executive functioning. The effect sizes were from small to medium. These findings supported the efficacy of a classroom-based, teacher-implemented, SCERTS model-based intervention.

In contrast with the widespread use of the SCERTS model in the West, its application in China has been limited. Consequently, there has been a lack of evaluation studies on the effectiveness of the SCERTS model in helping Chinese children with ASD. A recent research project in Hong Kong launched by Heep Hong Society has contributed to filling this gap. The project involves (1) a training program on the SCERTS model for professionals and parents; (2) the implementation of the SCERTS model-based

intervention; and (3) an evaluation study that examined the effectiveness of the SCERTS model-based intervention in training preschool children with ASD. The project’s procedures are depicted in Fig. 1. The following paragraphs report details of the training program, the SCERTS model-based intervention, and the evaluation findings.

The first part of the program offered training to educators from 10 special childcare centers in Hong Kong where interests in learning and applying the SCERTS model had been indicated.

A total of 65 professionals, including special education teachers, physiotherapists, speech therapists, and occupational therapists attended the training. The training program consisted of two major components. The first component was a 2-day training workshop on the SCERTS model for all special education teachers ($N = 34$). The second component was a 3-day advanced training workshop on the SCERTS model for all the therapists (11 physiotherapists, 10 speech therapists, and 10 occupational therapists). In addition, a 2-h training workshop was provided to parents of the

Effectiveness of a SCERTS Intervention, Fig. 1 Procedure of the project. (Reprinted from *Effectiveness of a SCERTS Model-Based Intervention for Children with Autism Spectrum Disorder (ASD) in Hong Kong:*

A Pilot Study, by L. Yu and X. Zhu, 2018, *Journal of Autism and Developmental Disorders*, 48, p. 3797). Copyright 2018 by Journal of Autism and Developmental Disorders

children in the 10 centers in order to help the parents understand the rationale of the SCERTS model, the basic ideas underlying it, and its application in the daily lives of children with ASD. After the training, all participating professionals implemented the SCERTS model-based intervention in their respective centers (Yu and Zhu 2018).

With regard to the implementation of the SCERTS model-based intervention, the 10 centers were randomly divided into two groups. Professionals in Group 1 implemented a 10-month intervention with 35 h of training per week; Group 2 implemented a 5-month intervention with the same number of hours of training per week. The training in both groups included (1) the special education teachers' daily teaching and (2) individual therapy and group treatment sessions provided by therapists on a weekly basis. In each center, a special education teacher taught five to seven children, while the size of the group treatment session was four to six children. The 5-month intervention (Group 2) was implemented 5 months after the commencement of the 10-month intervention (Group 1) (Yu and Zhu 2018).

Two measures were taken during the intervention period to ensure and monitor the quality of the program's implementation. Firstly, a 2-week coaching session on the application of the SCERTS model in the intervention practices with 6 h of observation and 2 h of case discussion each day were provided for special education teachers in the 10-month and 5-month groups, respectively. Secondly, three times during the intervention period, a total of eight trained professionals observed the implementation of the SCERTS model-based intervention at each center. A quality indicator scale was used to rate the extent to which each indicator was met in the areas of program planning, implementation, monitoring, adjustment, and transactional support including both learning and interpersonal support. Each item was rated on a 4-point scale: 0 = no or minimal evidence that this is happening; 1 = this is happening some of the time (less than 50%); 2 = this is happening most of the time (more than 50%); and 3 = this is always happening (more than 90% of the time) (Yu and Zhu 2018). These scores were used to provide feedback and

suggestions to the program implementers and to help them to address any problems which had been identified. In this study, good intervention quality was observed in both groups.

At the same time, a mixed-method evaluation study was carried out (1) to examine the impact of the SCERTS model-based intervention on the participating children in different developmental areas, especially in the domains of social communication and emotional regulation; (2) to investigate the relationship between the duration of an intervention and its effectiveness; and (3) to understand the opinions of the intervention implementers and the parents of participating children. The first two aims were addressed in the quantitative part of the study, based on a quasi-experimental pre- and posttest design focusing on participating children. The third aim was addressed in the qualitative part of the study focusing on the intervention implementers and the parents of participating children.

For the quantitative part, 122 children (age = 53.43 ± 9.05 months) were successfully recruited from the 10 special childcare centers with the following inclusion criterion: (1) children had a clinical diagnosis of ASD; (2) children age between 3 and 6.5; and (3) their primary caregivers gave informed consent. The children were rated by a group of trained professionals who were blind to the study using standardized assessment tools. The assessment was conducted before the implementation of the 10-month intervention and after the completion of all intervention sessions. For the qualitative part, six focus group interviews were conducted after the interventions with 19 parents (three groups) and 20 professionals (another three groups) by researchers with knowledge and experiences of the SCERTS model. The interview sessions focused on what parents and professionals thought about the SCERTS model, the changes they observed in the children after participating in the program, and the impacts of the model on their own knowledge, skills, and attitude towards children with ASD.

The findings showed that children in both the 10-month SCERTS model-based intervention group and the 5-month intervention group performed significantly better in social

communication and emotional behaviors than they did before the intervention. Apart from improvements in the core deficits of ASD, participating children also demonstrated significant development in other areas, such as fine motor skills, gross motor skills, visual-motor imitation, as well as improved personal self-care, as reported by caregivers. It has been proposed that these additional child outcomes of the intervention may be attributed to the enhanced transactional support, which serves as another key element of the SCERTS model. The study also found that duration of intervention has little influence on the effectiveness of the SCERTS model-based intervention. The 5-month intervention had similar impacts to those of the 10-month intervention on the participating children's development, suggesting that the effects of the SCERTS model-based intervention can be observed in a relatively short period of time. This may further encourage parents and professionals to continue to adopt the SCERTS model-based approach in their daily practices. These findings provide empirical support for the effectiveness of the SCERTS model-based intervention in improving children's development in multiple domains, among a sample of preschool children with ASD in Hong Kong. Given the limited evidence on the effects of comprehensive treatment models on child outcomes (Odom et al. 2010), particularly in a non-Western cultural context, these findings are uniquely important.

The results of the focus group interviews reveal that both program implementers (i.e., teachers and therapists) and parents expressed positive views about the SCERTS model, both reporting significant improvements in the participating children in different developmental areas. The training and implementation of the SCERTS model also had a positive impact on their own attitudes and behaviors when working with children with ASD. Specifically, both parents and professionals considered the SCERTS model to be a well-designed training model with clear objectives, assessment measures, intervention procedures, and evaluation tools. Based on the model, children's individual developmental needs can be identified, and this helped different social partners

to design tailor-made support for the children. Teacher participants also reported that the emotional regulation and transactional support concepts were very useful and helped them to better understand the children's needs. Consistent with the findings of the quantitative part, professionals and parents observed improvements in the children's social communication skills and emotional regulation, such as improved understanding of basic emotion, and the ability to use behavioral strategies to express their feelings more frequently. Parents also reported an increased confidence in children's expression and communication. Some children became more fluent in their speech and used a clearer tone of voice in communication after implementation of the SCERTS model-based intervention.

Moreover, parents and professionals reported that the SCERTS model-based intervention project shifted the way they think about and work with children with ASD. The project encouraged them to reflect on how to better work with the children and how to meet children's developmental needs. They displayed a higher sense of self-efficacy, more acceptance about children's challenging behaviors, and adopted a more positive approach to providing the necessary support to children with ASD. Educators reported that their roles changed from being highly directive to being more facilitative when they were provided with the SCERTS model-based intervention. More choices and shared control between educators and children encouraged a better understanding of their role in learning, improved the structure of lessons, and led to less problematic behaviors. The learning atmosphere became more relaxed with improved teacher-child relationships, enabling professionals to pay more attention to the promotion of children's social communication skills and emotional regulation abilities. Overall, both educators and parents reacted positively towards the SCERTS model-based intervention. Both were guided to respond to the needs and interests of children with ASD, to modify the environment, and to use different approaches to facilitate children's learning. At the same time, emotional and educational support provided to parents and educators further

improved their self-efficacy and confidence in coping with the difficulties that they encountered and in promoting improvements in children's key deficit areas as well as overall development. The qualitative findings verified the quantitative results and further demonstrated that the incorporation of the SCERTS model in training children with ASD will benefit the children and the related partners around the child.

The positive findings and successful experience of this research project have several practical implications. Professionals and researchers who are working with children with ASD may consider further integrating the model into their existing programs and investigating the impact of the program. Furthermore, regular training on the SCERTS model for parents of children with ASD would be beneficial. Such training empowers parents to apply the model in their daily life in order to facilitate their child's development. Finally, the model can be used to help different partners to collaborate closely with each other when working with children with ASD. These collaborative practices not only benefit the children and their families; they also have the potential to bring about positive changes in the practices of professionals and other treatment partners.

Future Directions

As a comprehensive treatment model for children with ASD, the SCERTS model has been well operationalized but has as yet yielded limited evidence on treatment outcomes (Lin et al. 2016; Odom et al. 2010). While the extant studies have provided preliminary empirical evidence for the effectiveness of the model, there remains a pressing need to systematically examine the implementation and impact of other types of SCERTS model-based intervention with rigorously designed research. Important future research directions might include performing randomized control trials (RCTs) to examine how the SCERTS model-based intervention program could contribute to positive changes in children with ASD in different age groups (such as

preschool, school-aged, adolescents), after excluding the effects of maturation. RCTs also need to be undertaken for the purpose of further investigating the relationship between the duration of intervention and its effectiveness. Additional research is needed to complement existing findings and to examine the effect of the SCERTS model-based intervention on the basis of a more representative sample of children with ASD. The long-term effects of the SCERTS model-based intervention furthermore will be followed up in longitudinal studies. Last, but not least, parents play an important role in enhancing the effectiveness of the SCERTS model-based intervention program, and future study should also examine the mediation effect of parental practices on children's outcomes.

In sum, intervention based on the SCERTS model recognizes the broader context of a child's development. It has a positive impact not only on children with ASD but also on their parents, teachers, and therapists. The SCERTS model provides a useful framework of intervention that can be potentially applied in a variety of educational and treatment settings to help children with ASD.

Effectiveness of Parent-Child Interaction Therapy for Children With and Without Autism Spectrum Disorder

Kimberly Zlomke and Ashley Dawn Greathouse
Combined-Integrated Clinical and Counseling
Psychology Doctoral Program, University of
South Alabama, Mobile, AL, USA

Definition

Research and clinical experience suggest that a significant number of young children with autism spectrum disorder (ASD) present with coexisting clinically significant behavior problems. Children with ASD are often severely impacted in the areas of socialization, communication, repetitive behaviors, and restricted interests. The

impairment in communication and socialization may increase the risk for problem behaviors, making children with ASD more likely to display problem behaviors that warrant treatment. For children with ASD, an important social context for the development of both maladaptive, problem behaviors and adaptive, pro-social behaviors is the parent-child relationship, including parent-child interactions. Interventions that train parents to modify their interaction patterns often lead to positive behavioral changes in children with and without developmental disabilities. One intervention that has demonstrated effectiveness in typically developing young children and has a significantly growing research base for children with ASD for improving parent-child relationships, reducing problem behavior, and increasing child compliance is Parent-Child Interaction Therapy (PCIT). PCIT has been established as an effective, evidenced-based treatment for typically developing young children ages 2–7 with behavioral difficulties through highly specified, step-by-step, lived-coached sessions with both the caregiver and the child. Parent acquisition of skills taught in PCIT is gauged through the Dyadic Parent-Child Interaction Coding System (DPICS), and child behavior is typically assessed through parent report using the Eyberg Child Behavior Inventory (ECBI).

Historical Background

Behavioral Parent Training (BPT) programs are the most used and well-established treatments for children with externalizing problem behaviors. BPT programs train parents how to alter their child's behavior at home through behavior analytic techniques and principles. BPT programs have been shown to help alleviate symptoms of many disruptive behavior disorders and have additionally been shown to alleviate aggression and increase compliance in typically developing children. PCIT is one specific BPT program and is based on principles from attachment theory and social learning to promote an authoritative parenting style. Attachment theory informs the focus on a warm and responsive parent-child relationship

in order to develop a secure parent-child relationship. Social learning theory informs the behavioral techniques implemented within PCIT focused on consistent contingencies to alter dysfunctional interactions and patterns within the parent-child relationship. Theoretically, PCIT focuses initially on relationship enhancement (attachment) first as a necessary foundation for a later focus on effective limit setting, contingencies, and consistency in discipline. In PCIT parents learn to attend to positive behavior, ignore inappropriate behavior, and implement time-out for noncompliance and aggression.

Several treatment approaches have been used to improve the behavior, language, and social skills of children with autism, each with varied levels of empirical support. The more common and empirically supported include interventions based on applied behavior analysis, incidental teaching, errorless compliance training, and parent training (McDiarmid and Bagner 2005). PCIT incorporates a number of techniques that are traditionally seen in therapies addressing behavioral difficulties in children with ASD. Similar to Floortime and TEACCH, PCIT places a high degree of importance on consistent and high-quality parent-child interactions (Masse et al. 2007; Petrenko 2013). PCIT also shares similarities with pivotal response training in its emphasis of using familiar play objects, conducting training in an environment similar to the home, and a focus on generalization of skills (Masse et al. 2007). A common theme inherent within many interventions for children with ASD and what is often thought of as best practices for treatment of ASD (Smith and Iadarola 2015) is to take a comprehensive approach by allowing parents to play an integral part in therapy. By increasing parental involvement, skills learned within a clinic are then generalized to other settings such as the home and public environments. PCIT views the parent as the agent of change in a child's life. PCIT not only stresses the importance of relationship building through enriching and rewarding parent-child interactions but also contains an intensive compliance training component similar to the ABA discrete trial training.

The PCIT therapy protocol is structured in two phases, with the first focused on relationship enhancement (Child-Directed Interaction; CDI) and the second focused on parental consistency and discipline (Parent-Directed Interaction; PDI). Following a didactic parent-only session, parents are live-coached in the relationship building skills of **P**raise, **R**eflection, **I**mitation, **D**escription, and **E**njoyment (PRIDE). Coaching is continued until the parent reaches a specific level of mastery criteria in the observed skill use. Upon mastery of CDI skills, the therapist engages the caregiver in a didactic PDI teaching session followed by several PDI coaching sessions focused on the provision of effective commands, appropriate responses for child noncompliance, and strategies to increase compliance. PCIT employs a structured time-out technique as the primary discipline strategy. The taught time-out procedures can be individualized to the child and serve the purpose of eliminating a child's ability to escape a command before progressing with the parent-child interactions. The compliance training begins with the use of simple "play" commands prior to moving to more real-life instructions. Throughout PCIT parents review their progress on specific behaviors that are coded and graphed, are assigned homework activities, and are provided opportunities for independent problem-solving. Following therapy there is a graduation session where any additional resources are provided, and both the caregiver and the child receive certificates of completion.

Current Knowledge

PCIT is a widely recognized evidenced-based intervention for the reduction of child externalizing behaviors of typically developing children with over 25 years of research. Multiple meta-analyses of the effectiveness of PCIT for typically developing children support decreases in parental stress (Cooley et al. 2014) and in reduction in child behavior problem intensity (Cooley et al. 2014; Ward et al. 2016). Thomas et al. (2017) provided an updated comprehensive meta-analysis including both typically developing and

a variety of clinical populations such as children with mild to moderate intellectual impairment and developmental disabilities, preterm children, foster children, children with ADHD, children in Head Start families, and children who have experienced or are at risk for experiencing maltreatment. Findings suggest that PCIT is an effective means of reducing parenting stress and child problem behavior across a variety of child populations (Thomas et al. 2017).

Several single-subject design and small sample studies have examined the effectiveness of PCIT for children with ASD. All have reported a reduction in child problem behavior and an increase in positive parenting skills. Beyond child problem behavior and positive parenting skills, PCIT in the ASD population has been found to reduce maternal psychopathology (i.e., stress, depression, and anxiety), to increase child vocalization frequency, to decrease some ASD-related symptomology (e.g., atypicality and withdrawal), and to increase some ASD-related deficits (e.g., functional communication). Larger sample studies have decreases in child problem behavior with the ECBI and increases in positive parenting skills following PCIT for children with ASD (Furukawa et al. 2018; Parladé et al. 2019; Ros and Graziano 2019; Zlomke and Jeter 2019; Zlomke et al. 2017).

Future Directions

Although empirical evidence now supports the use of PCIT for children with ASD and coexisting disruptive behavior, several questions remain unanswered. Each study varies in their inclusion criteria, and by definition ASD is a heterogeneous diagnostic label. Therefore, future research should identify appropriateness of children with ASD for PCIT. It may be that certain language parameters, presence of self-injury, or other child characteristics may preclude the successful participation in PCIT.

Clinician tailoring of PCIT to a presenting parent-child dyad is standard practice. Given the unique presenting problems and symptoms present in children with ASD, variations in

implementation strategies, treatment targets, and techniques should be investigated. A proposed addition of a social-directed interaction (SDI) phase to the PCIT protocol would focus on communication abilities and social skills. A communication-focused SDI would incorporate command training and “when/then” statements. Communication targets could also include eye contact and greetings like “hello” and “good-bye.” PCIT with children with well-developed verbal abilities would possibly social skills targets (e.g., how to ask a question or get someone’s attention). In addition to the SDI phase, it has been recommended to add a time-out readiness phase after CDI and before PDI. The time-out readiness phase would allow for the specific teaching and practicing of compliance prior to the implementation of time-out. This phase would allow the child to gain access to expectations prior to time-out and allows the caregivers to practice their PDI skills prior to the implementation of time-out. During this time-out readiness phase, caregivers would also be taught physical prompting to achieve compliance without the use of time-out while they practice their skills, and the child experiences the compliance contingencies prior to experiencing time-out. Although these two suggested phases (social-directed interaction phase and time-out readiness phase) are currently untested, they may increase PCIT effectiveness and remain in the spirit of the theoretically based protocol.

Definition of Autism Disorders and Postural Control

Autism spectrum disorders (ASD) refer to a range of conditions that are characterized by pervasive problems in social interactions and atypical motor behaviors (American Psychiatric Association 2013). Children with ASD usually have sensory deficits affecting fine and gross motor behaviors (Fournier et al. 2010). One of the key element governed by sensory motor processes is keeping the posture upright (Doumas et al. 2016; Kohen-Raz et al. 1992). Successful postural control requires integration of vestibular, somatosensory, and visual input (Doumas et al. 2016). Abnormal postures such as toe walking, hyperextension of the neck, or arching the back have been reported among children with ASD (Kohen-Raz et al. 1992). These atypical postural behaviors play a detrimental role in daily life and negatively affect independence of children on the spectrum. This can further exacerbate core symptoms of ASD by restricting social interactions and limiting opportunities to acquire perceptual-motor skills (Memari, et al. 2014; Travers et al. 2013).

Keeping posture upright is a fundamental skill, which has been the focus of attention in motor research. Postural control is the ability to maintain center of mass (COM) in the base of support (Memari et al. 2013). Position of the exerted ground reaction forces to confront body weight is considered as center of pressure (COP) (Shumway-Cook and Woollacott 2001). COP as the well-known index of postural control is an indicative of neuromuscular reactions to the

motion of body mass which retains the stability. Previous studies have shown that as children grow up, they gain more skills in keeping posture upright and as a result postural sway decreases (Hytönen et al. 1993). This might be considered in clinical diagnosis to portray a cardinal feature of postural control immaturity for children with neurodevelopmental disorders.

Historical Background of Postural Control

It has been shown that children with ASD exhibit higher postural sway and show atypical patterns compared with their typically developing (TD) peers (Memari et al. 2013; Minshew et al. 2004). Contrary to TD children, those with ASD have higher instability in medio-lateral direction than antero-posterior direction, suggesting postural immaturity, or an asynchrony between muscle stabilizers, or an alternative mechanism for generating postural control (Fournier et al. 2010; Memari et al. 2013). Postural instability among children with ASD was more pronounced when the somatosensory input either vestibular or visual or both were disrupted (Goulème et al. 2017; Minshew et al. 2004). Increase in sensory information demand or task difficulty will result in more postural sway in both groups of ASD and TD. However, because children with ASD have problems in multimodal sensory integration, the difference is significantly accentuated in children with ASD (Doumas et al. 2016; Minshew et al. 2004; Stins et al. 2015).

Because in real-life situations postural control is usually accompanied by a cognitive secondary task such as an audio or visual task, investigating the dual task paradigm can help to uncover mechanisms of postural control. It has been shown that children with developmental disorders, Tourette syndrome, or ASD will show more postural sway in dual task conditions (Laufer et al. 2008; Lemay et al. 2010; Memari et al. 2014); however, findings in the TD population are mixed (Pellecchia 2003; Riley et al. 2005). This might be due to the difficulty of the task and cognitive load which is involved. When two tasks are involved, they will

compete to allocate more attentional resources within the limited attentional capacity. Therefore, children with developmental disorders such as ASD with restricted attentional resources show higher postural sway when the attention is divided during a concurrent task (Memari et al. 2014; Pellecchia 2003).

Considering different types of tasks, children with ASD exhibit higher postural sway in inspection task than visual searching task (Chang et al. 2010). They also showed higher postural instability in visual searching than audio digit span task (Memari et al. 2014). This might be an indicative of higher visual reliance among children with ASD to maintain balance (Molloy et al. 2003; Stins et al. 2015). Thus, executing simultaneous visual tasks or any manipulation on visual input during postural control will decrease visual attentional resources dedicated to postural control. This will lead to higher postural sway among children with ASD to a greater extent than among their TD peers.

Current Knowledge on Postural Control and Social Cues

Recently, uncovering effects of social stimuli on postural control has been an upsurge of interest. It seems that there is an interconnection between motor control system and affective system. Previous studies have shown that social cues can alter arousal level and affect postural control (Gea et al. 2014; Ghanouni et al. 2017; Hillman et al. 2004; Stins and Beek 2007). For example, TD children showed larger postural sway when viewing happy and sad faces compared with angry or neutral ones (Goulème et al. 2017). Also, viewing unpleasant pictures can decelerate heart rate, decrease postural sway, and induce muscle stiffness (Azevedo et al. 2005; Roelofs et al. 2010; Stins and Beek 2007). These physiological responses resemble the freezing-like maneuvers seen in threatening situations. Coarse and fast processing of threatful stimuli is rooted in survival and evolution. Therefore, increased backward postural sway as opposed to forward sway when viewing unpleasant pictures will show approach-avoidance motor responses to affective stimuli (Gea et al. 2014;

Lopes et al. 2009). However, the extents of this connection among individuals with developmental disorders such as ASD are yet to be explored.

Previous study has shown that children with ASD, compared with their TD peers, exhibit higher postural sway when viewing social stimuli such as faces versus objects (Ghanouni et al. 2017). Authors also found that the extent of postural sway is moderated by the severity of the autistic disorder. This is an interesting finding as children with ASD have problems in perceiving social stimuli and may experience higher arousal and anxiety in social contexts (Dalton et al. 2005). This might be the reason that children with ASD usually avert their gaze from facial stimuli. When children with ASD view social versus object stimuli, induced higher anxiety and arousal will lead to higher postural sway (Ghanouni et al. 2017; Horslen and Carpenter 2011).

According to the weak central coherence theory, individuals with ASD have a tendency and bias towards attending to details rather than looking at the picture as a whole (Happé 2013). Facial stimuli require configural or global processing, a task which children with ASD have problems in doing it (Behrmann et al. 2006). Therefore, it can be assumed that the high-cognitive task of facial processing will recruit more attentional resources among children with ASD compared with their TD counterparts. Due to the limited attentional capacity, the residual attentional resources will contribute to the postural control, which in return accentuates the postural instability observed among children with ASD (Karatekin 2004; Pellecchia 2003). However, further investigations on the underlying mechanisms of postural control among population with ASD are warranted. This might be a potential avenue for preparing a new diagnosis tool or a model to detect early signs of developmental disorders such as ASD.

Future Directions

Comparing mechanisms of development and impairments in postural control among individuals with and without ASD would help to

distinguish patterns of maturation, compensation, and abnormality. Currently, there is little information on how postural control is maintained or affected among populations with ASD. Using various environmental perturbations, cognitive tasks, and difficulty levels would be helpful to uncover mechanisms involved in the postural control among individuals with ASD. Difficulties in postural control among populations with ASD may be associated with the presence of other comorbid conditions such as attention deficit hyperactivity disorders. However, there is a dearth of literature on how comorbidity, age, intellectual functioning, gender, and autistic traits will modulate postural responses in various contexts. Future studies should consider evaluation of postural control in conjunction with psychological responses such as pupillary dilation, eye gaze, heart rate, and electromyography of muscles among populations with ASD to portray more robust pictures of these phenomena.

Efficacy of Group-Based Organized Physical Activity Participation for Children with Autism Spectrum Disorder

Katherine Howells¹, Carmel Sivaratnam¹ and Nicole Rinehart^{1,2}

¹Deakin Child Study Centre, School of Psychology, Faculty of Health, Deakin University, Geelong, VIC, Australia

²Faculty of Medicine, Nursing and Health Sciences, Monash University, Melbourne, VIC, Australia

Synonyms

[Group-based organized sport](#)

Definition

Physical activity is well recognized as movements produced by the body's skeletal and muscular system that require the expenditure of energy (World Health Organisation 2019). One subset of physical activity is group-based organized physical activity (OPA). This has been defined as physical activities typically involving formal and structured training sessions that are supervised by an adult coach (Okely 1999). This idea that OPAs are structured and planned in nature is consistent across Australian, UK, and US definitions. The

group-based aspect of this term also requires activities to involve two or more individuals (aside from the coach) engaging in the activity at once. These programs can include competitive team sports such as soccer or football and basketball or non-competitive programs such as group horse-riding and karate. Australian definitions also incorporate the idea that such activities are required to be organized by sporting bodies or recreational associations, for example, clubs and community associations (see Howells et al. 2019).

Importantly, group-based OPA and physical activity are not synonymous terms. Aside from increasing physical activity, group-based OPA and organized sports have been associated with added psychosocial benefits (Vella et al. 2016) above what an individual physical activity program such as walking can provide. This is particularly important for children with neurodevelopmental disorders such as autism spectrum disorder (ASD), where the salient features lie in social and communicative difficulties and individuals are at a heightened risk of psychiatric conditions such as clinically significant anxiety. The benefit to psychosocial domains following OPA, which is a movement-based activity, is unsurprising, not only because of the opportunity for social interaction with peers during the program but also because of the integration of neural circuitry between various developmental brain regions (e.g., frontal regions and the cerebellum). Hence, programs that develop motor skills also have the potential to benefit broader developmental areas such as social, cognitive, and behavioral functioning in children with ASD. Despite potential benefits, Canadian research shows children with neurodevelopmental conditions more generally often spend less time engaged in OPA, in comparison with TD children (Arim et al. 2012). Given this, it is imperative that children with ASD are provided with the same opportunities to participate in group-based OPA programs as their neurotypical peers, and research continues to explore factors which could hinder or facilitate participation in OPA in this group, alongside the potential benefits to participation. An increase in research may aid in the journey that sees these types of programs run in conjunction

with current clinical interventions for children with ASD. Moreover, while the potential benefits associated with physical activity more generally are broad ranging, participation in group-based OPA programs also provide children with ASD an opportunity to engage with peers and integrate into community activities. This may benefit not only the individual child but also their families, providing a sense of normalcy, and aid in attitudinal shifts at the community level.

Efficacy of Peer Network Interventions

Melissa A. Sreckovic

Education Department, University of Michigan – Flint, Flint, MI, USA

Definition

Peer network interventions are a type of peer-mediated instruction/intervention in which peers are selected to form a network around a student with disabilities, and regularly scheduled opportunities for the network to interact are provided during noninstructional times (e.g., lunch, between classes, before school) with ongoing support from an adult facilitator (Carter et al. 2013). Social outcomes are the primary goals of peer network interventions, including increasing opportunities for students to meet new people, supporting friendship development, and encouraging students to engage in social activities during and outside of school (Carter et al. 2013, 2014). To date, peer network interventions have been implemented primarily with students with autism spectrum disorder (ASD) in an effort to address social and communication challenges.

Two to six peers (i.e., peer partners) are selected to join the student with ASD, and together, they create the peer network. The desirable traits of a peer partner include a positive peer model (e.g., demonstrates age-appropriate social skills) who is excited and expresses an interest in developing a relationship with the student with ASD (Carter et al. 2014). Peer partners should also express interest in staying involved throughout the duration of the intervention. Facilitators can be any adult who has a positive relationship with the student with ASD including but not limited to, a general or special educator, paraprofessional, special area educator (e.g., physical education), speech-language pathologist, counselor, or extracurricular teacher/coach.

The components of peer network interventions are flexible (Carter et al. 2019) but typically include the following core components:

(a) orienting the students to the network, (b) scheduling regular opportunities for students to interact, and (c) providing adult facilitation (Carter et al. 2013). Before weekly scheduled meetings begin, an orientation is held where the peer partners and student with ASD meet, get to know one another, share schedules, identify areas of common interest, and learn about peer network goals and how the peer network works (e.g., Sreckovic et al. 2017). During weekly meetings, the facilitator checks in with students to identify if they are interacting outside of weekly meetings (e.g., walking to class together) and encourages students to connect outside of meetings (Carter et al. 2013). The majority of the meeting is centered on a shared activity selected by the students, such as playing a game. The facilitator guides the meeting at the beginning of the intervention but slowly allows the students to take ownership over the meetings while still providing guidance when needed. For example, the facilitator may model how to engage the student with ASD in the activity or model how to use aided augmentative and alternative communication (AAC).

Historical Background

Individuals with ASD by definition have difficulty with social interaction and communication (APA 2013). These challenges, combined with segregated service delivery, close proximity of paraprofessionals and/or special educators, and peer attitudes and lack of understanding of ASD, make developing and maintaining positive peer relationships difficult (Carter 2018). Indeed, research consistently documents limited and low-quality peer relationships among students with ASD and their peers (Petrina et al. 2014), even though students with ASD have expressed interest in developing friendships with peers (Daniel and Billingsley 2010). This is concerning considering positive peer relationships make important contributions to success in school and overall quality of life (Rubin et al. 2009). On the contrary, peer rejection can lead to internalizing and externalizing behavioral problems (Ladd 2006)

and a myriad of psychological problems including loneliness (Buhs and Ladd 2001).

Examining the efficacy of social interventions to improve social deficits of individuals with ASD has been a long-standing focus in intervention research (White et al. 2017). While interventions to teach concrete social skills (e.g., social skills training) and communication skills (e.g., picture exchange communication) have been well established in the literature (Wong et al. 2015), less is known about the efficacy of generalizing those skills to natural environments, as well as how to create opportunities for individuals with ASD to develop positive peer relationships. Increased social skills do not necessarily equate to friendship development and greater social involvement in the school culture. In fact, in a nationally representative longitudinal study of the involvement of adolescent students with disabilities, students with ASD were reported as the least likely to receive telephone calls from friends, frequently see friends outside of school, and get invited to another student's social event (Wagner et al. 2004). Further, only 30% of the students with ASD participated in an organized group activity at school within the previous year (Wagner et al. 2004). Therefore, students with ASD may not fully participate in or benefit as much as they could be from the social aspects of school, such as establishing friendships and participating in group activities.

Given the low quality and quantity of reciprocal friendships and high bullying victimization rates among youth with ASD, identifying interventions that support increased social interaction and the development of positive peer relationships are now at the forefront of research (Winchell et al. 2018). Peer-mediated instruction/interventions naturally increase physical proximity between students with ASD and their peers as teachers systemically teach peers strategies for interacting with and/or helping students with ASD learn new skills (Wong et al. 2015). While peer-mediated instruction/interventions have been identified as an evidence-based practice with empirical evidence supporting social (birth to age 22) and academic (age 6–22) outcomes of youth and young adults with ASD (Wong et al.

2015), less is known about the efficacy of specific forms of peer-mediated instruction/interventions, such as peer network interventions.

Current Knowledge

Peer network interventions have been implemented in elementary (e.g., Kamps et al. 2014;), middle (e.g., Haring and Breen 1992; Koegel et al. 2012), and high (e.g., Gardner et al. 2014) school settings as a stand-alone intervention (e.g., Sreckovic et al. 2017) and as part of a multicomponent packaged intervention (e.g., direct instruction, scripted practice, peer-mediated free play, review of performance, and reinforcement; Kamps et al. 2014). The efficacy of peer network interventions has been examined using single case (e.g., Hochman et al. 2015), randomized controlled trial (e.g., Asmus et al. 2017), and quasi-experimental (Schmidt et al. 2017) research designs.

Across K-12 settings, peer network interventions have been efficacious at improving social outcomes for students with ASD with varying support needs, including students with complex communication needs (Biggs et al. 2018), students with significant support needs (Asmus et al. 2017), and students with ASD without comorbid ID (Sreckovic et al. 2017). Research indicates they have been implemented with high school students with ASD with diverse characteristics (e.g., autism symptomology, adaptive behavior, IQ scores) and education pathways (i.e., standard diploma, alternative diploma; Carter et al. 2019). Educators have implemented peer network interventions with fidelity and rated the interventions favorably, identifying them as feasible to implement, useful, and effective for their students with ASD and ID (Carter et al. 2019).

Across studies available in the literature, the components of peer network interventions maintain relatively consistent with core components including orienting students (e.g., preparing peer partners to effectively communicate with focal students), regularly scheduling opportunities for students to engage in a shared activity, and

incorporating adult facilitation. Yet, intervention procedures have been implemented flexibly to meet the needs of students and facilitators. The frequency of network meetings and length of intervention have also differed across studies. For example, participants in the study conducted by Asmus et al. (2017) met approximately once per week at least six times throughout the semester (Asmus et al. 2017), and participants in a study conducted by Sreckovic et al. (2017) met twice per week for 4 weeks. The efficacy of peer network interventions has been investigated with several outcome variables, all under the social/communication domain. These outcome variables include initiations and responses to/from peers/focal student (Haring and Breen 1992; Kamps et al. 1997, 2014, 2015; Koegel et al. 2012, 2013; Sreckovic et al. 2017), duration of social interaction among students (Garrison-Harrell et al. 1997; Kamps et al. 1997; Koegel et al. 2012, 2013), communicative acts toward peers (Mason et al. 2014), appropriate social responding, extended social interactions (Haring and Breen 1992), social interactions, social engagement, social-related goal, adult facilitative strategies (Gardner et al. 2014; Hochman et al. 2015), support behaviors from peer partners (Gardner et al. 2014), interaction quality (Haring and Breen 1992; Gardner et al. 2014), social contacts, friendship gains, social skills, school activity involvement (Asmus et al. 2017), proximity to peer partners, peers, adults (Biggs et al. 2018; Gardner et al. 2014; Hochman et al. 2015) and proximity to AAC device (Biggs et al. 2018), use of augmentative communication system (Garrison-Harrell et al. 1997), total number of words spoken, number of different word roots, length of conversational turn in reciprocal conversation, ratio of different words to total words (Schmidt et al. 2017), interactions with peers (symbolic and nonsymbolic) and nonprompted, symbolic communicative acts (Biggs et al. 2018), and bullying victimization (Sreckovic et al. 2017).

In a seminal peer network study, Haring and Breen (1992) investigated the efficacy of peer network interventions implemented with two junior high students (one student with ASD and

one student with ID and language delay). During the intervention, each focal student was grouped with four to five typically developing peers to form a network. Peer partners walked with the focal students in between classes, ate lunch with the focal students, and once a week the facilitator and network met to talk about times to interact, assess the group's satisfaction, and casually interact. Using a multiple baseline across participants design, the researchers measured social interactions, appropriate social responding, and extended social interactions. During intervention, the frequency of appropriate social interactions increased between the focal students and their peers. Further, both focal students participated in non-prompted events outside of school with their peer networks. One focal student's mother noted her son had been invited to an event outside of school by a peer for the first time. After the intervention, 89% of the peer partners rated focal students as a friend, and 11% rated focal students as a best friend. Subsequent work has replicated this study with the addition of treatment fidelity and demonstration of experimental control. Illustrations of studies across the K-12 continuum are included below.

Supporting evidence in elementary settings.

Several studies have examined the impact of peer network interventions on the social outcomes of young children with ASD. Kamps et al. (2015) investigated the impact of peer network interventions implemented with 95 kindergarten and first grade students with ASD. Four to six peers were selected from each focal student's class or a class within one grade level to serve as peer partners. The peers rotated throughout the week; two peer partners participated per meeting. The intervention consisted of direct instruction on a social skill (e.g., sharing and requesting), child-adult practice, peer-mediated free play (10–15 min of play with toys and games), and review of performance and reinforcement. The researchers employed a block randomization procedure by class to examine the impact of the intervention on total communication acts (i.e., initiations and responses) to peers, language performance, adaptive communication, and teacher impressions of children's social

communication. Children in the comparison group received instruction as indicated in their IEP and were not receiving structured peer-mediated social skill instruction. When compared to the control group, the implementation of the intervention resulted in statistically significant growth over time for initiations to peers during nontreatment social probes and generalization. Children with ASD were more likely to engage in more communicative acts the longer they were in the peer network intervention. At the end of first grade, no statically significant differences were found for initiations or responses across groups. Language performance and adaptive communication skills improved for all students over time, but those in the peer network group tended to see greater gains compared to the control group. Teacher's impressions of children's social communication also improved as a result of the peer network intervention. Overall, treatment fidelity averaged 86% with a range of 15–100%.

Using a small sample of participants from Kamps et al. (2014, 2015), used a multiple baseline across participants design to investigate the effects of peer network interventions implemented with four students with ASD (ages 6–7) on communicative acts to peers. The same intervention procedures were used as Kamps et al. (2015). Treatment fidelity averaged 84% across participants. Results demonstrated clear increases from baseline to intervention for all four participants for total communicative acts (i.e., initiations and responses) to peers, and Tau results indicated a statistically significant increase from baseline to implementation for total communicative acts. Generalization probes were higher in the intervention phase compared to the baseline phase for all three participants (generalization data were not gathered for one participant). Intervention implementers noted they felt the intervention was feasible and indicated they noticed improvements in focal students' interactions with trained and non-trained peers as reported on social validity forms.

While Kamps et al. (2014, 2015) implemented peer networks with students with ASD who demonstrated functional verbal

communication, peer network interventions have also been implemented with students with ASD who used aided AAC. Biggs et al. (2018) investigated the effects of a peer network intervention and an aided AAC modeling component using a multiple probe across participants design with two intervention phases. The interventions were implemented with three students with ASD and one student with ID who had significant cognitive impairment and aided AAC. Participants were in third or fourth grade, and 13 peers participated as peer partners. The peer network intervention consisted of an orientation meeting for the peer partners and focal students and peer network meetings where students participated in a shared activity held twice a week during lunch for three participants and during indoor recess for one participant. During the second phase of the intervention, a peer-implemented aided AAC modeling component was added to the peer network intervention. This consisted of an initial training meeting to teach peers how to use aided AAC modeling and coaching support for peers during at least two network meetings. Dependent variables were interaction with peers (i.e., symbolic and nonsymbolic communicative acts), symbolic communicative acts that were nonprompted, frequency of peers' interactions, frequency of peer-aided AAC models, modes of symbolic and nonsymbolic communication, and focal student proximity to peers, adults, and AAC device. Treatment fidelity averaged 96.1% across sessions. Results indicated a functional relationship between the implementation of the peer network and increased interactions between peers and the focal students. A functional relationship did not exist between the implementation of the peer network and nonprompted, symbolic communication to peers. When the peer-implemented aided AAC modeling component was added, nonprompted, symbolic communication increased, except for one participant whose peers used aided AAC modeling during the first intervention phase. Generalization data indicated peer interaction was higher than during pre-baseline probes and baseline phase but lower than during intervention.

Supporting evidence in secondary settings.

Peer network interventions have been implemented in secondary settings, which is both timely and needed as the prevalence of students with ASD in secondary settings now matches that of younger cohorts (Blumberg et al. 2013), and the social demands and expectations in middle and high school become more complex. Hochman et al. (2015) used a multiple baseline across participants' design to examine the efficacy of peer network interventions on social interactions, social engagement, social-related goal, proximity to peers and adults, and facilitator support behaviors. Four male students (age 15–17) with ASD and ID participated in the study as focal students, and 11 students participated as peer partners (2–3 peers per network). The intervention consisted of an orientation meeting for the peer partners and focal students and weekly meetings in the cafeteria. During weekly meetings, students ate, participated in a shared activity, talked about a selected topic, reflected on how meetings were going, shared ideas for new activities, discussed upcoming events they could do together, and reported interactions outside of weekly meetings. The implementation of the peer network intervention resulted in increased social engagement and peer interactions for all students, substantial gains related to the social-related goal for one student, and increased proximity to peer partners and decreased proximity to students with disabilities. Generalization data for both social engagement and peer interactions returned to near baseline levels for three out of four focal students. All peer partners and focal students considered each other as friends after the intervention. Treatment fidelity data were collected from an observer, coach, and facilitator. Social validity data indicated the facilitator and peer partners wanted to participate again and felt focal students benefited socially. Focal students and parents responded positively, and focal students wanted to be involved in the future.

Sreckovic et al. (2017) replicated Hochman et al. (2015) using similar intervention procedures but implemented the intervention with three high school students with ASD without comorbid

ID. Using a multiple baseline across participants with probe assessments during baseline design, the following dependent variables were investigated: initiations and responses from students with ASD to peers and from peers to students with ASD. Bullying victimization was also examined as an exploratory variable using the Bully Victimization Scale (Reynolds 2003) at four time points. Peer networks consisted of one student with ASD and three to six peer partners. All students participated in an orientation meeting (description of what a peer network is) and introduction meeting (a time for students to meet, exchange schedules, and identify common interests). Each network met approximately twice per week during lunch in an empty classroom or conference room. During weekly meetings, the facilitator encouraged students to connect outside of meetings, informally assessed student satisfaction, and provided guidance as needed as students played a game of their choice. A functional relationship was demonstrated between the implementation of the peer network intervention and total social interaction (i.e., initiations and responses from students with ASD to peers and from peers to students with ASD). Maintenance data were similar to intervention for all participants, and mean responses to and from students with ASD during generalization were greater than baseline for all three participants. Bullying victimization decreased for two participants, although changes were minimal for one student. Treatment fidelity data for the facilitator averaged 100% across sessions, and 98% across sessions for peer partners. All peer partners, parents, and school staff rated the intervention favorably, and two focal students rated intervention favorably.

Using a randomized controlled trial design, Asmus et al. (2017) examined the efficacy of peer network interventions implemented with 95 high school students with severe disabilities and 192 peer partners (3–6 partners per network). Adolescents with severe disabilities qualified for the state's alternate assessment and/or received special education supports under the category of ID or ASD and were educated for at least one class in general education settings. Twenty-one high

schools across two states were included in the study. Intervention procedures were similar to those in Hochman et al. (2015) and Sreckovic et al. (2017); however, a peer partner training was held without the focal students. Networks met approximately once per week and participated in a shared activity (e.g., meal, game) and planned times throughout the week to connect. In the comparison condition, students were included in at least one general education class with support from a paraprofessional or special educator and received services as stated in their individualized educational programs. Social contacts and friendship gains, social skills, and school activity involvement were examined. Treatment fidelity data averaged 95.9%. Results indicated students in the intervention group reported meeting outside of weekly meetings with the focal student an average of 11.4 times. Students who participated in the intervention had significantly more social contacts throughout the day and gained significantly more friends without disabilities by the end of the semester compared to students in the comparison group. No significant effects were found on parent-reported measures of out of school social connections. During the following semester, 33% of the peer partners reported a social contact with the focal student, and 41% reported they were friends. Teacher reported friendships and social contacts between students with severe disabilities, and those without disabilities at one semester follow-up were significantly higher for students in the intervention condition compared to the comparison condition. Further, students in the peer network condition had an average of 1.51 more social contacts and an average of 1.35 more friends than their counterparts in the comparison condition. No significant differences were found at two semesters follow-up. No significant differences were found for parent-reported social contacts and friendships at one or two semesters follow-up or for school activity involvement. Based on the evidence at both the elementary and secondary levels, peer network interventions are empirically supported as efficacious in improving social and communication outcomes.

Future Directions

All students, with or without ASD, should benefit from both the academic and social opportunities embedded in authentic educational settings. Implementing interventions to facilitate social interactions and friendship development is imperative to help students with ASD succeed socially and benefit from the positive consequences associated with supportive peer relationships (e.g., Rubin et al. 2009). A review of the literature highlights the positive social outcomes (e.g., increased social interaction and friendships with peers without disabilities) that result from implementing peer network interventions and areas of future research. As the efficacy base continues to expand, future research teams are encouraged to consider the following research recommendations.

First, peer network interventions consist of several components that are flexible to meet the needs of the focal student. Research teams are encouraged to conduct component analyses to examine the extent to which each component is necessary to yield desired outcomes. Further, intervention length ranged across studies (e.g., 1 month, one semester; one meeting per week, three meetings per week). Research is needed to determine optimal intervention intensity and dosage (e.g., recommended length of intervention and optimal meeting contexts) that result in desirable and generalizable outcomes.

Second, while several studies included generalization probes, these findings varied. More research is needed on how to maintain impact over time. Further, more research is needed on the long-term outcomes of peer network interventions. Longitudinal studies are needed to determine effects at 1-year follow-up. Similarly, more research is needed on friendship development both within and outside of the peer network. Do students with ASD develop reciprocal friendships with their peer partners and with other peers and does their social network centrality change after the peer network intervention is introduced?

Finally, research teams are encouraged to examine the impact of peer network interventions

beyond the K-12 education setting. Peer networks may be efficacious in work settings to increase sustainability in employment, in post-secondary education settings to increase participation in campus life, and in community settings to increase community engagement and overall quality of life.

In summary, the field has greatly expanded with regard to peer network interventions for youth and adolescents with ASD. The intervention has proven to be flexible, feasible to implement, and efficacious at improving social/communication outcomes for students with ASD across the K-12 continuum. Without targeted interventions and intentional efforts to foster meaningful relationships for students with ASD, students with ASD are unlikely to develop relationships (Carter et al. 2008). Therefore, implementing targeted interventions, such as peer network interventions, is imperative to support the social success of students with ASD.

Efficiency (Behavioral Assessment)

Jessica Rohrer

The Center for Children with Special Needs,
Glastonbury, CT, USA

Definition

Efficiency refers to the principle that responses which require less effort and produce more reinforcement will occur more frequently than responses that require more effort and produce the same or less reinforcement. Responses that take less effort and produce a similar level of reinforcement as more effortful responses are considered to be more efficient. To increase the likelihood that a desired behavior will occur, the environment or other antecedents can be

manipulated to increase the efficiency of the response (decrease the response effort), therefore making the response more likely. To decrease the likelihood that an undesirable behavior will occur, the efficiency of that response should be decreased (increase response effort), therefore making it more likely that the individual will engage in competing behaviors that require less effort.

Synonyms

[Response effort](#)

Definition

Response effort is the amount of effort that a person must put forth to successfully complete a specific behavior. The amount of effort required to complete the behavior has an impact on the frequency at which that behavior will be emitted. If two responses result in fairly equal reinforcement, the behavior that requires less response effort is more likely to occur than the behavior that requires more response effort.

Egypt and Autism

Nagwa Abdel Meguid
Research on Children with Special Needs,
National Research Centre, Cairo, Egypt

Historical Background

Egypt is located in North Africa, bordering the Mediterranean Sea, between Libya and the Gaza Strip. Genetic diseases in Egyptians have been known since the days of the pharaohs as recorded in the ancient history. Gene flow to Egyptian population occurred from Greco-Roman, Arab, Turkish, French, and English settlers. For reasons of custom, tradition, culture, and socioeconomic benefit, consanguineous marriages occur in approximately half, and first-cousin marriages occur in *one third of Egyptians* (Yamamah 2012). The population of the region is characterized by large family size, high maternal and paternal age, and a high level of inbreeding with consanguinity rates. Women are continuing to bear children until menopause increasing the predisposition to inherited disorders.

Developing countries are facing an alarming gap between innovations in childhood learning and developmental disabilities (LDD) research and their delivery to communities. Important problems include illiteracy (especially among women), lack of job opportunities (especially for young people), and slow economic growth because of loss of traditional economies, low productivity, and lack of innovation and competitiveness.

There is a critical gap in autistic spectrum disorder (ASD) research with respect to manifestations of the condition in developing countries.

This gap is now attaining public health significance. On one hand, they prioritize the control and eradication of infectious diseases and reproductive maternal health. On the other hand, LDD research receives scant attention and almost no funding from donor agencies that specialize in addressing the problems of developing nations.

While Egypt has shown considerable progress in the prevention and combating of infectious diseases, genetic disorders remain a major health problem. There are no comprehensive data on disabilities currently available. The importance of medical genetics in pediatric departments of Egyptian universities was well appreciated in the early 1960s at Cairo and Ain Shams Universities in Egypt. At 1966, Prof. Samia and her colleagues started the specialty of human genetics at the National Research Centre (NRC) followed by molecular genetics at 1985 (El Awady and his colleagues at the NRC). In 1967, medical genetics unit (Prof. Suzan Rushdy and her colleagues) was established at the Medical Research Institute in Alexandria. This was followed by the initiation of medical genetics units in other universities such as El-Mansoura (Prof. Mohamed Hafez). Mubarak City of Scientific Research encompasses centers for frontier sciences including genetic engineering and biotechnology. Human genetic courses are now introduced in the curriculum of medical students in most universities. Specialized postgraduate degrees in the field of medical human genetics are offered to graduates from medical schools in Egypt at Ain Shams and Alexandria Universities. Training programs given by specialized geneticists from different institutions are offered to physicians from the Ministry of Health and Population.

On the other hand, Egypt has 19 medical schools; all of them have psychiatric departments, some of which are departments of neuropsychiatry. They have offered a master's degree in psychiatry for the past 25 years and a doctorate for the past 20 years. In general, there are few psychiatrists specializing in childhood problems (Okasha 2004). Nowadays, there are psychiatrists and psychologists specializing in the mental health needs of people with mental retardation. This is the case in Egypt where people with mental retardation

and mental disorders are seen by general psychiatrists, pediatricians, and other professionals without specialist knowledge of their problems. Prevalence of autism spectrum disorders among children with developmental disorders in Egypt was documented to be 33.6 % (Seif eldin et al. 2008). This preliminary finding needs to be corroborated and extended, in conjunction with better descriptions of normal early childhood development. There is a need for both community and school-based studies on epidemiology of autism spectrum disorders in Egypt.

The pioneer works on autism spectrum disorders in Africa had been by Longe and Asuni (Longe and Asuni 1972) and Lotter (1978, 1980) about three decades after the first report of autism spectrum disorder by Kanner in 1943 (Kanner 1943). With the rise in the prevalence of autism spectrum disorders (ASD) in the Arab countries, the development of an Arabic tool for early diagnosis and intervention was sought as part of an effort to better understand the prevalence of this disorder. The Modified Checklist for Autism in Toddlers (M-CHAT) was chosen (Seif Eldin et al. 2008).

Many factors may contribute to the substantial underdiagnosis of ASD cases in developing countries. One of the factors is the difficulty in obtaining a diagnosis, as the pediatricians are often inexperienced in the diagnosis and management of these disorders. The lack of awareness among parents regarding ASD, including a failure to recognize symptoms and seek diagnosis and treatment, is also likely to be a factor, especially in cases of children with mild forms of the disorder (Al-Farsi et al. 2010). Most of the children diagnosed with autism belonged to families of low socioeconomic standards with unsatisfactory income, in Egypt and Jordan, along with a lower paternal education level (Mostafa et al. 2012).

Legal Issues, Mandates for Service

The condemning of women who are obligated to continue her pregnancy with disabled outcome is indicative of our society's prejudice against disabled people and women. Egyptian women were

expected to stay at home, take care of the children, and let their husband bring home the paycheck. Most of them were dominated by the man of the house, providing whatever the man dictated, food on the table when they come home, house cleaned, kids taken care of, and anything else handled. Egyptian women suffer from various forms of stigma manifested during marital and social events, schooling, and employment. The stigma linked with being mothers of a disabled child is so deeply rooted that it plays a central role in many aspects of their life. Many mothers felt they had “lost” aspects of their personal identity, with the role of motherhood dominating how they felt about themselves and how other people viewed them. One of the most influential factors in those cases is the socioeconomic constraint. When both parents have a good socioeconomic state, they have a different level of thinking and can rationalize the fact it is nobody’s fault their child was born with special needs, and they believe there are several ways to help him/her and support him/her, and most probably, they do have few means to help supporting him/her and start to isolate themselves away from their friends and other family members. The cases where the father decides to leave mostly show (in all the cases I’ve seen) that the parents are not highly educated and some have a rather low financial status. The father then can easily blame his wife for this child and simply leave them to start a new life elsewhere with new wife, leaving them with no financial support and certainly no emotional support.

As a challenge to the family, autism must rank among the most stressful of childhood developmental disabilities. The autistic disorders require the practitioner to work with different types of subjects, including the patient, the parents and other caregivers, those working in the school system, and other professionals involved in mental health. In our current understanding of the phenomena of identical gene copies for children of first-cousin marriages, will inherit identical gene from each parent in 1/16 of their gene loci ($F = 0.0625$), giving birth to disabled children. However, the prevailing culture and ignorance lead the society and husbands to blame the women who

bear disabled children because of this. The condemning of women who are obligated to continue her pregnancy with disabled outcome is indicative of our society’s prejudice against disabled people and women. Also, the burden of care is a matter of socio-structural constraints rather than only emotional distress.

In developing countries, basic needs such as nutrition, water, and sanitation often overshadow mental health concerns. In many developing countries, up to half of the population is children (Hong et al. 2004; Robertson et al. 2004). The difficult circumstances found in many countries violate the basic rights of children (Robertson et al. 2004).

The government of Egypt places a high priority on disability, with governmental and non-governmental organizations working together to solve disability issues. However, current services cover only 10% of the total number of persons with disabilities. Services in Egypt are still limited in spite of the new policy of deinstitutionalization and the provision of community care. Community care in the form of hostels, day centers, rehabilitation centers, and health visitors is only available in major cities. Mental health legislation was introduced in Egypt in 1944, in advance of most other Arab and African countries (Okasha 2004).

The chronic nature of autism can be draining to some parents, and there is a risk of parents becoming exhausted. Attitudes of the two parents toward the female were more negative. According to the 1975 Rehabilitation of Disabled Persons Act, any type of business that has over 50 employees must include at least 5% of people with physical or mental disabilities as part of their total workforce. Although on paper people with autism are supposed to be included, but much like with all other mental and physical disabilities, the reality is from what the law stipulates.

The Ministry of Education issued a minstrel decision in April of 2009 to include 10% of children with special needs in mainstream schools, with no more than four of those children in each class. Those 10% are around 152, 800 children out of an estimated seven million people born with disabilities in Egypt. However, there are not enough trained professionals to deal with

people with disabilities in general, let alone with a complex disorder such as autism. Launching our own awareness campaign against the stigma associated with mental illness should be addressed.

Special schools for intellectually disabled: These schools are free of charge and are situated in the major cities in the greater Cairo area. They accept students with mild intellectual disability. Also, some private schools have opened classrooms in their schools to serve intellectually disabled children. Those schools charge high fees and usually accept mild cases. The high prices of most of the services cannot be afforded by many families. However, there is an unfair geographical distribution of services provided to intellectually disabled individuals. Most of the services are situated in Cairo, although 64 % of the mentally challenged live in rural areas and countryside. We have shortage of professional manpower such as specialized doctors, nurses, psychiatrists, psychotherapists, teachers, etc. which is a major barrier against the spread of the rehabilitation programs in Egypt.

Parents having an autistic child will pass through several coping stages, namely, denial, anger, and guilt, bargaining, and finally acceptance; they must deal with the grief they feel over absence of healthy imagined child (King et al. 2006). Coping is a process of readjusting attitude, feeling, perception, and beliefs about self and others, while coping style is a particular coping mechanism used repeatedly by a person in different situations. Among Egyptians, maladaptive coping strategies are mechanisms used to reduce a person's emotional response to stressful circumstances in a short term, but lead to greater difficulties in the long term; moreover, the treatment services available for late adolescents and adults with autism are quite limited.

Epidemiological data are important for the development of public policy and programs to improve children's mental health. Epidemiological research answers the following questions (Leibson et al. 2001): How many children in the community have mental health problems? How many children make use of mental health services? What is the distribution of mental health

problems and services across age, sex, and ethnic group? Are there historical trends in the frequency of child mental health problems? What is the developmental course of mental health problems from childhood to adulthood? What etiological factors can be identified to inform the design of prevention and treatment programs? How cost-effective are child mental health services? What are the outcomes for children who receive services? The answers to these questions provide a rational basis for service design and implementation.

Overview of Current Treatments and Centers

Epidemiological surveys are viewed as a priority that extends beyond the need for objective and robust estimates of prevalence. These provide additional valuable benefits as they often result in systematic information regarding existing services and may help in assessing the needs and priorities for Egyptian community. Epidemiological studies themselves may also eventually provide revealing findings regarding the manifestation of PDD across cultures.

A review of global [prevalence](#) of ADS by Elsabbagh et al. (2012) reported a median of 62 cases per 10,000 people with average 4.3:1 male-to-female ratio. There is a lack of evidence from low- and middle-income countries. We could not identify published data on population-based estimates of prevalence of PDD from Egypt.

Level of knowledge and awareness about autism spectrum disorder is low among the general population and health care workers in Egypt. There is need for community education of the general population and continuous medical education for health care workers on issues relating to autism spectrum disorder. This would enhance early recognition and interventions and in turn improve prognosis. The mothers of autistic children are vulnerable to psychological distress; families have been burdened by financial concerns, worries about health of autistic children (Elbahnasawy and Girgis 2011).

Cohen and Volkmar (2005) reported that parents typically are active partners in their children's education to ensure that skills are learned in the educational program; they transfer to the home setting and teach their children many behaviors that are best mastered in the home and community. Regional variation in parental education may still determine their help seeking for autism (Seif Eldin et al. 2008) and that it is predominantly severe cases that are currently being identified in developing countries like Egypt and more specifically in poor communities. We recommend that continuous health education and counseling programs are necessary to improve mothers' coping patterns toward care of their autistic children. Feeling skilled and informed is needed to mother's sense of competence, their ability to make the right decisions, and their ability to support their child's well-being and development to lessen their stigma.

There are more than 50 Egyptian Association of Autism – Egyptian schools (egyptian-schools.com/en/schools/egyptian-association-of-autism/). Examples are Autism Solutions (www.autismaspirations.com/), Autism: Preschool (readingroom.mindspec.org/), and Autism Is Treatable (www.tacanow.org/).

The purpose of these schools is to provide helpful information about autism and tools and strategies to achieve positive interactions and increase learning for all members of the school community. They tried to provide valuable information for general education and administrative school staff, aides, office staff, bus drivers, nurses, custodians, classmates, and family members who interact with students with autism. Most of the successful schools and associations are nongovernmental and of expensive costs, so in fact services are often “paid out of pocket.” The Ministry of Health is urged to launch a comprehensive program to improve the status of autistic children in Egypt. Recently, teachers and support personnel in schools sporadic in the Egyptian community have been recognized and increased (Abdel et al. 2012). However, most of them are not qualified, some are mothers of autistic children, and others attended training workshops supervised by unqualified

nonspecific personnel, which are more a myth than a reality. School-based consultation services for child mental health do not operate regularly to the extent required in developing countries. This gap leads to a failure to prevent school dropout and other significant consequences.

Overview of Research Directions

Of the 84.6 million people living in Egypt, 29 % are children under age 15. Until recently, identification and treatment of child mental health problems have not been a high priority in Middle East countries.

Although autism occurs in all cultures and countries, most of the published researches have come from Western countries. Little is known about its clinical correlates and comorbidity in Middle Eastern and Arab countries (Al-Salehi et al. 2009). Publications on child psychiatry, in particular, on topics such as autism were found to be underrepresented among Egyptian population. Very low research is yet to investigate the **effects of culture on autism**; effect of culture among Egyptian and Saudi population suffering autism on the age of diagnosis and seeking for intervention of autism was studied by Hussein et al. (2011). They concluded that the age at diagnosis and at the commencement of intervention was lower in the Egyptian group. The Saudi group showed a higher percentage of missing examinations, older birth order, and significantly higher preference to drug treatment, while the Egyptian group showed a high preference to behavioral and phoniatric therapies, higher paternal and maternal education, higher employment among parents, and higher family concern. They highlight that cultural context may significantly influence the age of detection and the age of starting the intervention.

There are few studies investigating the parents' attitudes toward their autistic child (Obaid 2012). The medical community in the Middle East needs to redouble its efforts to ensure early diagnosis and the best intervention in children with autism. In Egypt and North Africa, there has been a

fivefold decrease in child mortality in recent decades. This success has also come with a push to improve the quality of life for children and foster their development during the early years of life. This includes recognition of autism, a condition long hidden in much of the Arab world.

Hussein et al. (2012) reported that most parents first sought the advice of pediatricians for their child's mental health problem, and a substantial number consulted traditional healers. They recommend that awareness programs targeting pediatricians and elementary school teachers are urgently needed in Egypt to shorten the duration of undiagnosed illness among children.

The Arab world lacks centers to collect and organize Arab medical documents and to disseminate the available information.

A study on increasing people awareness with the aid of health team professionals in prompting tolerance and understanding of autism was done by Elbahnasawy and Girgis (2011). On the other hand, studying the environmental risk factors of autism was reviewed by El Baz et al. (2011). They reported that low birth weight and delivery by caesarian section were significantly higher among cases than controls. In addition to hypoxia, resuscitation and history of jaundice were considered significantly risk factors for autism.

Nutritional assessment and complementary intervention in autistic children represent one aspect for researchers in Egypt. A pilot study done by Allam et al. (2008) was done investigating the effect of scalp acupuncture and language in autistic children. They find out some improvement in expressive language when combined with language therapy. Meguid et al. (2010a) reported an article investigating the potential role of vitamin D in autism through serum level assessment. They concluded that serum values of 25(OH)D in the children with autism of this study could classify them as being "vitamin D inadequate," which lends support to the hypothesis that autism is a vitamin D deficiency disorder. Another study by Ibrahim and El-Sayed (2012) discussed the role of dietary imbalances in the incidence of developmental disorders mainly conditions considered as leading

causes for abnormal nervous system development and altered function. They emphasized the need of dietary supplements. Iron metabolism alteration as a risk factor for several neurodegenerative disorders was investigated by Gebril and Meguid (2011). They reported on a pilot study for the association of HFE polymorphisms and autism. They did not find association of autism with the genes they worked on and recommended to include other iron metabolism genes.

While many aspects of autism remain poorly understood, major advances have been made in terms of **highlighting the genetic part** in advanced countries (Abrahams and Geschwind 2008) and few scanty publications from Egypt (Novarino et al. 2012).

Till date, research in autism in Egypt is sporadic regarding different issues:

Different studies on **the brain of autistic children** were done; a study to assess white matter integrity of autistic preschool children with diffusion-weighted MR imaging was done by Abdel Razek et al. (2013). The study was carried out on 19 autistic preschool children. They reported that the apparent diffusion coefficient value is helpful in the assessment of the integrity of the white matter in autistic preschool children and well correlated with CARS score, social age, and language age. Another study was done by Mostafa et al. (2008) where they proposed that autoimmunity to brain could play an etiopathogenic role in autistic patients. The frequency of serum anti-myelin-associated glycoprotein antibodies, as an index for autoimmunity to brain, and their relation to family history of autoimmunity were investigated in 32 autistic and 32 healthy matched children. They shed light on the etiopathogenic role of anti-myelin-associated glycoprotein antibodies and the role of immunotherapy in autism. The third Egyptian study regarding brain morphology of autistic children was done by Meguid et al. (2010b). Fragile X syndrome shares most of the behavioral phenotypic similarities with autism. How are these similarities reflected in

brain morphology? A total of ten children with autism and seven with fragile X syndrome underwent morphological (T1) 1.5-T magnetic resonance imaging (MRI). The authors found no significant difference in total brain volumes, regional volumes, gyrification index, sulcal depth, and cerebral cortical thickness. However, children with autism showed significant decrease in the medial prefrontal bilaterally and the left anterior cingulate cortices. Regression analysis revealed positive correlation between the medial prefrontal cortical thickness and the social IQ. The authors suggest that the difference between the two groups in the medial prefrontal and anterior cingulate cortices thickness may entail an altered social cognitive style. Functional MRI studies directly differentiating between social indifference (autism) and social avoidance (fragile X syndrome) are needed to further characterize the spectrum of social abnormalities between these two groups. Future functional MRI studies, with their noninvasive in vivo capacity in measuring the social behavior phenotypes and in correlation with the FMR1 gene, are needed to advance the efforts to elucidate the genetic and neural mechanisms underlying social behavior disturbances in fragile X syndrome and autism.

Meguid et al. (2007) found that the prevalence of fragile X syndrome among Egyptian males is 0.9:1,000, constituting for 6.4% among mentally subnormal males.

The prevalence of ADS among Eastern Mediterranean is as follows: 29/10,000 in the United Arab Emirates (Eapen et al. 2007), 1.4/10,000 in Oman (Al-Farsi et al. 2010), and 6.3/10,000 in Iran (Samadi and McConkey 2011).

The relatively low prevalence in the Omani and Iranian studies was attributed to prevalence caused by underdiagnosis and underreporting of cases resulting from limited access to service centers (Al-Farsi et al. 2010).

Defective antioxidant enzymes and increased lipid peroxidation in Egyptian children with autism have been studied and reported by Meguid et al. (2011).

Neuroimmunological Aspect of Autism

Immunological disorders are one of several contributing factors that have been suggested to cause autism. Kawashti et al. (2006) detected circulating IgA and IgG autoantibodies to casein and gluten dietary proteins done by enzyme immunoassays (EIA). Circulating IgG antibodies to measles, mumps, and rubella vaccine (M.M.R) and cytomegalovirus were also investigated by EIA in a sample of 30 autistic Egyptian children. They concluded that autoimmune response to dietary proteins and deficient immune response to measles, mumps, and rubella vaccine antigens might be associated with autism, as a leading cause or a resulting event. Further research is needed to confirm these findings.

Mostafa and Kitchener (2009) studied the frequency of antinuclear antibodies in 80 Egyptian autistic children and their relationship to a family history of autoimmunity. They found out that antinuclear antibody seropositivity had significant positive associations with disease severity, mental retardation, and electroencephalogram abnormalities. The study recommended that autoimmunity may play a role in a subgroup of children with autism. Another study by Mostafa and Shehab (2010) investigates the link of C4B null allele to autism and to a family history of autoimmunity in Egyptian autistic children. They concluded the possible link of C4B null allele to autism and to a family history of autoimmunity highlighting the possible contributing role to autoimmunity in autism.

Recently, the link between some alleles on human leukocyte antigen system and autistic children was investigated by Mostafa et al. (2013). They highlighted the probable protective association of HLA-DRB1*03 allele with autism. It warrants a replication study of a larger sample to validate the HLA-DRB1 genetic association with autism. This is important to determine whether therapeutic modulations of the immune function are legitimate avenues for novel therapy in selected cases of autism.

Social Policy and Training

Local authority training programs which help to spread knowledge and understanding should aim at extending expertise at different skill levels and to different sectors and should be open to all staff, not restricted for teachers only. In addition, recording of conferences and other sessions should be made available using high technology as webcasts so that they can be more accessible to a larger audience. Schools training policy should include an audit of existing skills, autism-specific qualifications, and training needs and should provide planning to meet those needs. Staff should be funded to participate in accredited courses in autism.

Eisenberg, Leon

Fred R. Volkmar

Child Study Center, Irving B. Harris Professor of Child Psychiatry, Pediatrics and Psychology, Yale Child Study Center, School of Medicine, Yale University, New Haven, CT, USA

Name and Degrees

Leon Eisenberg received both his BA and MD degrees from the University of Pennsylvania. He completed an internship at Mt. Sinai before

teaching briefly at the University of Pennsylvania. Following work as a psychiatrist in the US Army, he became a resident at Sheppard Pratt Hospital before beginning child psychiatry training at Johns Hopkins.

Major Appointments (Institution, Location, Dates)

- Johns Hopkins University: Baltimore, MD, 1953–1967, Instructor, Associate Professor, and Professor and Chief of Child Psychiatry.
- Harvard University, Cambridge, MA, 1967–1993, Professor of Psychiatry, Chair Department of Social Medicine and Health Policy, Maude and Lillian Presley Professor of Social Medicine, Emeritus status in 1993.

Major Honors and Awards

- Leon Eisenberg was the recipient of numerous honorary degrees and awards; some of the major awards include the Richmond award from the American Academy of Pediatrics, the Thomas W. Salmon Medal from the New York Academy of Medicine, and Juan José López Ibor Award from the World Congress of Psychiatry. In addition, several awards have been named in his honor. In 2009, the Leon Eisenberg Chair of Child Psychiatry at Children's Hospital Boston was named in his honor.

Landmark Clinical, Scientific, and Professional Contributions

Dr. Eisenberg conducted the first follow-up study (with Leo Kanner) of children with autism. Other accomplishments included his role in the first randomized control study of psychopharmacology in children and the first randomized controlled trial of stimulants in adolescents and of brief psychotherapy. He had long-standing interests in the social brain and in social medicine including an active role in working with Physicians for Human Rights.

Short Biography

A child psychiatrist and medical educator, Dr. Eisenberg was an original contributor to a series of innovations in the field of child psychiatry. These included, in collaboration with his mentor Leo Kanner, MD, some of the first follow-up studies of children with autism, in development of randomized clinical trials (RCTs), evidence-based medicine, and social medicine and international advocacy including for human rights.

Dr. Eisenberg followed Leo Kanner as the leader of child psychiatry at Johns Hopkins until his retirement there in 1967. At that time, he moved to Harvard University where he assumed leadership of the child psychiatry program. In 1974, he was appointed the Maude and Lillian Presley Professor of Psychiatry and, in 1980, became chair of the Department of Social Medicine and Health Policy until his retirement in 1993 when he became emeritus. He remained an active researcher and advocate until shortly before his death.

Elavil (Amitriptyline)

Karthikeyan Ardhanareeswaran
Autism Program, Child Study Center, Yale School of Medicine, New Haven, CT, USA
Program in Neurodevelopment and Regeneration, Yale School of Medicine, New Haven, CT, USA
Department of Molecular, Cellular, and Developmental Biology, Yale University, New Haven, CT, USA

Synonyms

Amitriptyline; Endep; Levate

Definition

Elavil is a tricyclic antidepressant (TCA). By blocking their reuptake by presynaptic neurons, TCAs increase the synaptic levels and action durations of noradrenaline and serotonin. Serotonin is an inhibitory neurotransmitter that is heavily involved in mood and emotion regulation and has been found to be elevated in the whole blood and platelets of ASD patients. In addition to their reuptake-inhibiting properties, TCAs also exert antagonistic effects on histamine H₂, serotonin 5-HT₂, α₁-adrenergic, and muscarinic acetylcholine receptors. While many of these neurotransmission systems have been implicated in autism pathogenesis, the generally low receptor specificity results in a high toxicity profile. Side effects include nausea, drowsiness, weakness, dry mouth, changes in appetite or weight gain, constipation, blurred vision, increased sweating, and decreased sexual drive. Low doses of this drug do show promise in the treatment of hyperactivity, impulsivity, aggression, and self-injury in ASD patients. However, further substantial validation is still required. A Cochrane review in 2012 did not currently recommend the use of tricyclic antidepressants for the treatment of individuals with autism spectrum disorder.

Elderly with Autism Spectrum Disorders

Matthew Bennett and Emma Goodall
The University of Wollongong,
Wollongong, NSW, Australia

Definition

Kanner's sentinel article *Autistic Disturbances of Affective Contact* focused on children, and this autism research and inquiry has been focused on children and adolescents on the autism spectrum (Jang et al. 2014; Kanner 1943; Perkins and Berkman 2012; Wise et al. 2017). However, as our knowledge about the autism spectrum has increased, more research about adults and elderly people with this condition is emerging. This entry begins with an overview of the proportion of age cohorts which are examined in autism research. It will then summarize the small amount of published research about elderly people on the autism spectrum. This will be followed by an explanation for why this population is rarely researched and areas where more research about this age cohort could be useful in meeting individual needs as well as wider public health goals.

Historical Background

Since the publication of Kanner's writings about autism, there has been a systematic and ongoing effort to examine children with autism, resulting in a dearth of research about other cohorts. In 2014, Jang and colleagues published a study where they calculated the proportion of age cohorts in autism articles which were published from 1994 to 2004. They collected and analyzed

2857 articles from 7 journals which specialized in publishing articles about the autism spectrum. They excluded letters to the editor, meta-analysis studies, and systematic literature reviews. Participants were classified and assigned to one of the four age categories: infants/toddlers (0–3 years), children (4–9 years), adolescents (10–19 years), and adults (>20 years, with further breakdown for those over 60). Jang et al. (2014) found that 94% of all studies ($n = 2688$) which they collected and analyzed examined infants, toddlers, children, and adolescents (between 0 and 19 years of age). In contrast, 3% of studies ($n = 75$) examined adults on the autism spectrum aged 60 years or older. Jang et al. (2014) concluded that most of our knowledge about the autism spectrum has been obtained from infants, children, and adolescents. Furthermore, based on this finding, Jang et al. (2014) proposed that more research should be conducted on the adults since most of a person's life occurs in adulthood.

Current Knowledge

There are publications which have reviewed the types of research published about elderly people on the autism spectrum (Bennett 2016; Happé and Charlton 2012; Patra 2016; van Heijst and Geurts 2015; van Niekerk et al. 2011; Wright et al. 2013). Bennett (2016) cited five studies about elderly people on the autism spectrum which examined executive functions and memory, diagnostic instruments used to identify Asperger syndrome in seniors, and diagnosing depression in elderly people with Asperger syndrome. Happé and Charlton (2012) published a literature review focused on articles which explored elderly people on the autism spectrum. The studies which they collected were assigned to one of three categories: (1) case studies of elderly people on the autism spectrum, (2) discussion papers which outlined the challenges of diagnosing autism in seniors, and (3) articles explaining empirical findings from surveys of studies about elderly people with autism. Patra (2016) published a systematic literature review of studies

about seniors on the autism spectrum stored on the PubMed electronic citation database. They identified 12 English language studies which met their inclusion criteria. The oldest study which they retrieved was published in 2013, and the most recent study was published in June 2016. The studies which they examined explored the physical health, psychological well-being, and cognitive or social functioning of elderly people with autism. Finally, van Niekerk et al. (2011) published a systematic review of studies about the instruments used to diagnose the autism spectrum in elderly people. They searched for relevant articles on PubMed, PsychLIT, and EMBASE which were published from 1996 to December 2009. They identified three studies which met their inclusion criteria. These studies examined all showed the importance of identifying the autism spectrum in the elderly and explained the long-term consequences of not identifying this condition within the elderly. In summary, there is a paucity of literature about elderly on the autism spectrum.

Aside from systematic literature reviews, studies have also examined the executive functions and memory abilities of elderly people with autism (Geurts and Vissers 2012). Geurts and Vissers's (2012) study compared the neuropsychological profile of elderly adults on and not on the autism spectrum. They sampled 23 elderly adults on the autism spectrum (18 males, 5 females; mean age = 63.6 years, SD = 7.5 years) and 23 elderly adults not on the autism spectrum (18 males, 5 females; mean age = 63.7 years, SD = 8.1 years). In addition, out of 23 elderly adults on the autism spectrum, 16 had Asperger syndrome, 2 had autism, 1 had a diagnosis of pervasive developmental disorder-not otherwise specified, 1 had an autism spectrum disorder diagnosis, and the remaining 3 had autistic tendencies. In comparison to those not on the autism spectrum, Geurts and Vissers (2012) found that elderly people on the autism spectrum had deficits with their working memory and had different cognitive profiles and trajectories of cognitive development.

Jang et al. (2014) posited that most studies about the autism spectrum focused on children

rather than adults or elderly. It is possible that a barrier to research around elderly people is less likely to have been diagnosed with an autism spectrum disorder. According to Bennett (2016), current assessment processes and instruments used to diagnose autism have not been tailored to identify autism in the elderly. Often an autism diagnosis is based on a mixture of clinical tests, clinical observations of the patient, and the patient's family providing the clinician with a description of their relative's behaviors. For patients who are elderly, however, such an approach might not be effective in diagnosing autism. During old age, elderly people often live alone or in nursing homes where regular contact with immediate or extended family members is limited (Bennett 2016). Additionally, James et al. (2006) explain that the questions which clinicians use in autism diagnostic assessments for children might not be appropriate for seniors. For example, while a clinician might be able to diagnose a child with autism by asking him/her questions about his/her friendships, such questions might not be applicable for seniors because their social network is smaller and they might have less social contacts. Furthermore, Geurts and Vissers (2012) explain that the clinical tests used to diagnose children on the autism spectrum are difficult to translate and apply to elderly people on the autism spectrum. Finally, Mukaetova-Ladinska et al. (2012) explain that, aside for developing tests to diagnose the autism spectrum in the elderly, there is also a need to develop cognitive and behavioral assessment tools for elderly people who are on the autism spectrum.

Future Directions

Despite the small amount of literature about elderly people on the autism spectrum systematically increasing each year, there are still many areas of research to be explored (Bennett 2016; Happé and Charlton 2012; Hategan et al. 2017; Totsika et al. 2010). Bennett (2016) proposed that the impact of nursing home care programs on elderly people on the autism spectrum is an area yet to be researched. In addition, Happé and

Charlton (2012) explained that social isolation often has a detrimental impact on elderly people not on the autism spectrum. However, it is unknown if seniors on the autism spectrum who engage in solitary hobbies and interests, which they find enjoyable and motivating, can somehow shield themselves from the negative impacts of social isolation. Michael, a person on the autism spectrum, has also voiced views about the importance of researching elderly people on the autism spectrum (Michael 2016). According to Michael (2016), very little is known about how elderly people on the autism spectrum manage medical conditions which occur during middle or older age, such as arthritis, menopause, type 2 diabetes, and some types of cancer. Similarly, Kats et al. (2013) published a study about clinical problems which older adults with autism and an intellectual disability exhibited. They found that there was an urgent need for research about the nature and treatment of behavioral problems in elderly on the autism spectrum. Finally, Perkins and Berkman's (2012) article showed that people on the autism spectrum have a lower life expectancy than those not on the autism spectrum. However, it remains unknown why there is a life expectancy discrepancy.

While increasing our knowledge and understanding about elderly people on the autism spectrum is a sensible goal, it cannot, however, be perused without support. Researchers may also struggle to work with elderly adults on the autism spectrum to gain an insight into their lived experience which may impact on their willingness to research in this area. Communication and emotional difficulties can be exacerbated in old age, and there has been little impetus to look at the well-being or economic costs of this growing population so far.

Piven and Rabins (2011) explained that a prolonged, integrated, and multipronged approach is required to study seniors on the autism spectrum from a psychological, sociological, and economic perspective. Piven and Rabins (2011) also propose that clinical and research training programs should develop ways to attract and retain early career researchers, from a diverse range of disciplines, to study elderly people on the autism

spectrum. Similarly, Bennett (2016) suggested that governments should increase funding for projects which can evaluate healthcare systems and services for seniors on the autism spectrum. Support services which are effective will be of benefit to both elderly on the autism spectrum and the wider community in terms of improving social outcomes and increasing economic efficiency.

Although there have been many recent developments in the study of elderly on the autism spectrum (Wise et al. 2017), there remains many areas where additional research can be conducted (Amanullah and Rajeh 2019). For example, despite literature showing that the elderly are often financially (Wajnberg et al. 2020) and physically abused (Yon et al. 2020), there is a dearth of literature about these topics for elderly on the autism spectrum. In the future, researchers should explore if senior citizens on the autism spectrum encounter greater rates of elder abuse than those who are not on the autism spectrum. They might possibly experience greater rates of elder abuse since their social difficulties might leave them with greater vulnerabilities (Flynn and Healy 2012).

As Bennett (2016) has explained, most of the children currently living with an autism spectrum diagnosis, at current the focus of research, will inevitably become elderly. If the amount of research about elderly people on the autism spectrum does not increase, then today's children on the autism spectrum may be disadvantaged in their old age. Furthermore, if there is a lack of research about elderly on the autism spectrum in the future, then the needs of elderly people with this condition will become the subject of speculation. To avoid this speculation altogether, and to help future generations of elderly people on the autism spectrum, it is crucial that research about the autism spectrum in old age continues to increase.

Electroconvulsive Therapy (ECT)

Nathalie Szilagyi

Yale Child Study Center, New Haven, CT, USA

Synonyms

ECT

Definition

Electroconvulsive Therapy (ECT) is a medical procedure in which a seizure (convulsion) is

induced via the external application of brief, focused electrical current in order to effect alterations in the electrophysiology of the brain with the goal of mitigating severe psychiatric symptoms. Although the exact mechanism of action remains unclear, evidence suggests that ECT may produce changes across multiple domains, including neuroendocrine systems, neurotransmitter tone and activity, and neuroplasticity. For example, studies have provided evidence that ECT potentiates the effects of the neurotransmitters serotonin, norepinephrine, and dopamine and increases cortical Gamma-Aminobutyric Acid (GABA) concentration. ECT has also been shown to be a strong inducer of dendritic arborization and new cell formation in the hippocampus, as well as reducer of dendritic arborization and excitatory synapses in the amygdala. These findings are consistent with the clinical effects observed with ECT: improvements in depressive and manic symptoms and suicidality, mitigation of catatonia, and decreased severity of some Parkinsonian symptoms. More recent studies have also reported decreased frequency of self-injurious behaviors after ECT.

Per guidelines from the American Psychiatric Association and the American Academy of Child and Adolescent Psychiatry, ECT may be indicated for the treatment of adolescents and adults with persistent, significantly disabling or life-threatening mood disorders such as depression or mania, psychosis, or catatonia refractory to other treatment modalities. ECT can also be used to treat neuroleptic malignant syndrome, a rare but potentially fatal condition that can occur in patients taking neuroleptic medications. Inadequate evidence exists regarding the use of ECT in preadolescents. However, multiple studies across decades of research in adolescents and adults have shown ECT to have efficacy superior to other treatment modalities for indicated conditions, with response rates for severe, intractable mood disorders, and catatonia as high as 80%.

More recently, researchers have reported success in using ECT to decrease severe, repetitive

self-injurious behavior in both typically developing patients with psychiatric comorbidities and patients with Autism Spectrum Disorder (ASD). As noted in other sections, repetitive, restricted, and stereotyped behavior is a primary feature of ASD. In up to 25% of individuals with ASD, such behavior is manifested as self-injurious behavior (SIB), which can range from occasional, mild episodes to frequent, unrelenting, and severe behaviors, leading to potentially serious injuries. Stereotyped movements also form part of the diagnostic criteria for catatonia, and some researchers have posited that catatonia has been historically underdiagnosed and inadequately treated in individuals with ASD. In fact, several large studies have estimated that 12–18% of autistic adolescents and young adults exhibit some symptoms of catatonia. While first-line treatments for SIB and catatonia include medication and (for SIB) behavioral interventions, some individuals present with severe and disabling symptoms refractory to these treatments. Although more research is needed, ECT may be considered as an option in patients with such refractory symptoms in order to decrease patient distress and avoid potentially catastrophic outcomes.

There are no absolute medical or neurological contraindications to the use of ECT, though certain CNS tumors, active chest infections or cardiac conditions are relative contraindications. Likewise, there are no psychiatric comorbidities or developmental disabilities which would be contraindications to the procedure when it is otherwise indicated. ECT has been shown to be a relatively safe procedure in modern use, well-tolerated by most patients receiving treatment. Modern ECT is performed under brief general anesthesia, and the reported mortality rate of up to four deaths per 100,000 treatments is believed to be primarily due to the risks associated with the general anesthesia. Of note, the mortality rate of ECT remains significantly lower than mortality rates for the intractable depression, mania, and catatonia for which ECT is indicated. Common side effects after ECT sessions include transient headache, nausea, fatigue, confusion, difficulties

in learning, and memory loss. Of these, memory loss has often been reported to be the most troubling to patients, and although it is most often transient or self-limited, there have been credible reports of persistent or even permanent memory loss, though usually limited to the time period around treatment. A course of ECT for acute psychiatric symptoms usually includes from 6 to 20 treatments, with the number of treatments generally determined by each patient's response to treatment and tolerance of the procedure. Some patients also appear to benefit from maintenance ECT to provide ongoing relief and prevent recurrence of symptoms.

Synonyms

[Electroencephalography](#)

Definition

An electroencephalogram is a graphical representation of the brain's electrical activity. In human assessment, electrodes are placed at various locations on the scalp. As neurons in the brain fire, these electrodes capture the resulting voltage, which is then amplified and recorded. This electrical activity oscillates quite rapidly. The number of oscillations over a phase of time can be measured and are termed “frequency.” Variations in frequency have been historically quantified in terms of oscillations per 1-s period as hertz (Hz). Common categorizations of frequencies include alpha (8–13 Hz), beta (13–30 Hz), gamma (30–600 Hz), delta (≤ 4 Hz), theta (4–8 Hz), and mu (8–13 Hz).

A subtype of electroencephalography examines changes in brain activity time-locked to particular events, termed event-related potentials (ERPs). ERPs are generally assessed in small windows of time, in the tens and hundreds of milliseconds.

Elementary and Secondary Education Act (No Child Left Behind)

Kristin Ruedel

Department of Special Education, University of Maryland Washington State University, Richland, WA, USA

Definition

The No Child Left Behind (NCLB) Act of 2001 is the most recent reauthorization of the

Elementary and Secondary Education Act (ESEA). It was signed into law on January 8, 2002, and received an overwhelming bipartisan majority in both the House and the Senate. NCLB represents the most significant expansion of the federal government into education in our history as it has dramatically increased federal mandates and requirements on states, school districts, and public schools. The Obama administration released its blueprint for revising the Elementary and Secondary Education Act (ESEA) on March 13, 2010.

The primary goals of NCLB are to increase achievement of all students in American public schools; reduce the achievement gap based on race, ethnicity, language, socioeconomic status, and disability; and ensure that students in every public school achieve important learning goals while being educated in safe classrooms by well-prepared teachers.

NCLB is based on the following key principles:

1. *Accountability for results:* By the 2005–2006 school year, each state must test students annually in grades 3 through 8 in reading and math and students in grades 10–12 at least once in reading and math. Every student will be assessed according to each state’s standard for proficiency in reading/language arts, math, and science by the end of the 2013–2014 school year. Student test scores must be made accessible to parents and communities. Test score data must be disaggregated by identified subgroups such as race/ethnicity, socioeconomic status, and disability. Schools that do not demonstrate “adequate yearly progress” (AYP) in student proficiency levels at large and within each of the subgroups must provide students with supplemental services such as free tutoring or after-school assistance.
2. *Parental choice:* Schools must provide parents with a report about the overall achievement of students in the school their child attends, the qualifications of their child’s teacher, and school safety. Parents of children in schools that are not making AYP for at least two consecutive years have the option of transferring their child to an alternate school within the school district. Parents also have the right to transfer their student if the school their child is attending is considered persistently dangerous or if their child has been a victim of a violent crime.
3. *Teacher quality:* Each state must develop a plan to ensure that all teachers of core academic subjects will be highly qualified by the end of the 2005–2006 school year. Highly qualified means that each teacher has full certification and a bachelor’s degree and has passed a state-administered test on core academic subject knowledge.
4. *Scientifically based methods of teaching:* There is an emphasis on the use of scientifically based methods of teaching under NCLB. Schools that fail to meet adequate student achievement goals are required to use scientifically based instructional methods in order to remain open.
5. *Local flexibility:* NCLB grants states and school districts with unprecedented flexibility in how they use federal education funds under NCLB in order to permit school districts to respond to specific local problems.

Elgar, Sybil

Adam Feinstein

Autism Cymru and Looking Up, London, UK

Major Appointments (Institution, Location, Dates)

Sybil Elgar was a pioneer in the education and care of both children and adults with autism both in the United Kingdom and internationally. As Lorna Wing has written, Elgar was “the UK’s first autism-specific teacher and an inspiration to those who knew her, at a time when autism was still ill-defined and widely misunderstood.” In 1964, Sybil Elgar and the newly formed Society for Autistic Children (now the National Autistic Society) managed to purchase premises to open the world’s first residential school for children with autism, in Ealing, West London. Elgar was a pioneer twice over, as she also founded Somerset Court, the first residential community for adults with autism, in Brent Knoll, Somerset, in 1974.

Major Honors and Awards

Sybil Elgar was a founding member of the British National Autistic Society. She was awarded member of the Order of the British Empire (MBE) in 1975.

Landmark Clinical, Scientific, and Professional Contributions

There is some evidence to suggest that the structured approach which forms the basis of TEACCH – one of the main educational

approaches to autism used worldwide today – was inspired, at least in part, by Sybil Elgar’s pioneering work in the United Kingdom. Dr. Eric Schopler, who founded TEACCH in North Carolina in the 1970s, visited the Sybil Elgar School in the United Kingdom in the previous decade and was very impressed by what he saw.

Short Biography

Sybil Lilian Elgar was born in Willesden, North West London, on June 10, 1914. After leaving school, she became a town clerk’s assistant before getting a job as a school secretary. She had no money to go to college, and staying at home to be with her then widowed and unwell mother, she took a Montessori teaching diploma as a correspondence course. Her interest in helping children was first sparked during her Montessori training when a visit to a hospital in London for “severely emotionally disturbed children” in 1958 left her deeply shocked. Elgar revisited the hospital in 1960 and, seeing that nothing had changed, decided to set up her own school, initially in the basement of her home. She developed a structured approach to teaching, giving her pupils clear and simple instructions and visual aids to ensure they understood what was required of them. Her methods ran counter to mainstream educational thought at the time. However, all the children in her class made substantial progress. Demand for her teaching rapidly grew, and in 1964, Elgar bought the premises to open the world’s first residential school for children with autism, in Ealing, West London. She also founded Somerset Court, the first residential community for adults with autism, in Brent Knoll, Somerset, in 1974. Elgar died on January 8, 2007, at the age of 92.

Eligibility (for Services Under IDEA/ADA, etc.)

John W. Thomas

Independent Educational Consultant, Durham,
NC, USA

Quinnipiac University School of Law, Hamden,
CT, USA

Definition

“Eligibility” in the context of this encyclopedia refers to qualification to receive reimbursement for or benefits from a variety of private and public programs.

Historical Background

Eligibility issues regarding ASD patients may present in private health care insurance, public health care insurance, education, disability benefits, and antidiscrimination contexts.

Current Knowledge

Private Health Care Insurance

Treatment for ASD can be costly, with annual expenses exceeding \$50,000 (NCSL) and mean lifetime care expenses totaling \$3.2 million (Ganz 2006). As a result, eligibility for private health insurance coverage for ASD-related treatment can be important to people with ASD and their families.

Insurance coverage is especially difficult to obtain for behavioral therapies such as Applied Behavioral Analysis therapy (ABA). Kaiser Permanente, for example, classifies ABA therapy as educational rather than clinical treatment and, thus, denies insurance reimbursement for its cost (Reinke 2008).

In response to insurance company reluctance to cover treatment for ASD, state legislatures have begun to address the issue. At this writing, the legislatures of 35 states and the District of

Columbia have enacted laws mandating some types of insurance coverage for the treatment of ASD. Statutes in 23 of those states – Arizona, Colorado, Connecticut, Florida, Illinois, Indiana, Iowa, Kansas, Kentucky, Louisiana, Maine, Massachusetts, Missouri, Montana, Nevada, New Hampshire, New Jersey, New Mexico, Pennsylvania, South Carolina, Texas, Vermont, and Wisconsin – make specific reference to treatment for ASD or autism. The remaining dozen mandate coverage for mental health conditions that may include ASD. The types of coverage mandated under these laws vary from diagnostic testing to a variety of therapies and treatment options. Some laws prohibit insurers from setting premium or coinsurance rates based solely on an ASD diagnosis.

State laws, however, are not applicable to all insurance policies. The federal Employee Retirement Income Security Act (ERISA) exempts self-funded, employer-provided health insurance plans from state coverage mandates (ERISA). As a result, in 2009, the United States Congress considered enacting the Autism Treatment Acceleration Act. But, the bill failed to pass either in the house of representatives or the senate. As of this writing, there is no federal mandate that insurers cover treatments or therapies for ASD.

Public Health Insurance: Medicaid

Conventional Medicaid Eligibility

Medicaid is a national health care program funded jointly by the federal and state governments. Adopted in 49 states and the District of Columbia and represented in the fiftieth state, Arizona, by a similar program, Medicaid provides services to the poor. Eligibility is largely limited to those with incomes no higher than the federal poverty level, with slightly higher incomes allowed for women, children, and other groups. Those who meet the income and other resource prerequisites qualify for a wide range of health care benefits, including treatment for ASD.

Services available to those with ASD vary by state. Medicaid insurers in some states cover a wide range of services, including Applied Behavioral Analysis (ABA). In other states, insurers are

more reluctant to cover ABA and other treatment modalities for ASD. In 2003, the Centers for Medicare and Medicaid Services issued a directive that characterized ABA as habilitative rather than rehabilitative and, thus, not mandatory coverage. In response, many state Medicaid agencies have ceased providing reimbursement for ABA (Mauch et al. 2011).

Medicaid "Waiver" Eligibility

All 49 states, the District of Columbia, and Arizona also participate in the Medicaid waiver program. Under these programs, parental financial resource limitations are "waived" for certain services for people under the age of 21 with developmental disabilities or long-term illnesses. These waiver programs cover home- and community-based services (HCBS). A person qualifies for HCBS services if he or she otherwise "would require the level of care provided in a hospital or a nursing facility or intermediate care facility for the mentally retarded" (42 U.S.C. § 1396n(c)).

Thirty states have ASD-specific waiver programs that delineate the specific services (Autism NOW). Connecticut's waiver, for example, covers "residential habilitation, personal supports, respite, clinical behavioral supports, supported employment, job coaching, community transition services, life skills coaching, community transition services or short term crisis stabilization to remain in their own home, family home or other community home."

Patient Protection and Accountable Care Act (PPACA)

By 2014, the PPACA, which congress enacted in 2010, will expand the Medicaid program to cover nearly all people with incomes up to 133% of the federal poverty level. The PPACA will also preclude Medicaid from considering in an eligibility determination resources other than income.

Disability Benefits

The Federal Social Security Program offers two types of disability benefits for which children with ASD may qualify.

Supplemental Security Income (SSI)

The SSI program provides monthly payments to children from birth to age 18. Children whose parents' income and other financial resources are within the statutory limits are eligible for benefits if they are not "engaged in substantial gainful activity" and are diagnosed with an impairment that meets SSI's disability definition for children. Listed impairments include "mental disorders," which encompasses ASD.

At SSI's enactment in 1973, the Social Security Administration (SSA) required for eligibility for benefits that a child's impairment be "comparable in severity" to an impairment that would qualify an adult for benefits. In 1996, congress modified the standard by enacting the Personal Responsibility and Work Opportunity Reconciliation Act of 1996 (PRA). This Act replaced the "comparable severity" standard with a test to determine whether a child suffers a "marked and severe functional limitation." Eligibility for benefits requires two findings. First, the child's impairment must be "medically determinable." Second, the impairment must "meet, medically equal, or functionally equal" a listed impairment (20 CFR §416.92 and §416.926a).

SSA regulations establish six "domains" to determine functional equivalence to a listed impairment: "acquiring and using information," "attending and completing tasks," "interacting and relating with others," "moving about and manipulating objects," "caring for yourself," and "health and physical well-being." A child must exhibit a "marked" limitation in at least two of these categories or an "extreme" limitation in one. Factors relevant to these determinations include "the child's age; the effects of treatment and/or medication; the effect of structured settings; the need for assistive devices or adaptations; school functioning, including attendance; time spent in therapy; the effects of chronic illness; and the combined effects of multiple impairments." An "extreme" limitation exists when the impairment or impairments "very seriously" interfere with the ability to initiate, sustain, or complete activities independently. This status is consistent with a

score three standard deviations below the mean on an applicable standardized test. A “marked” limitation exists when the impairment or impairments “seriously” interfere with those same skills. This status is consistent with a score of at least two but fewer than three standard deviations below the mean on an applicable standardized test.

The first step for determining eligibility for SSI benefits based on ASD, the “medically determinable” inquiry, requires a finding of deficiencies in “reciprocal social interaction and in verbal and nonverbal communication and imaginative activity, and a markedly restricted repertoire of activities and interests” (Ruskell). The second step typically finds “functional equivalence” to the “mental disorders” listing and resolves not on a finding of “extreme” limitation in a single domain but on a “marked” limitation in two domains, most commonly in “attending and completing tasks,” “interacting and relating with others,” “caring for yourself,” and “health and physical well-being.”

Finally, the ASD limitation must have existed for at least 12 months.

Social Security Disability Insurance (SSDI)

SSDI provides benefits to adults who have a disability that began before they reached the age of 22 years. Because they are based on the Social Security earning record of the beneficiary’s parents, the social Security Administration considers SSDI to be a “child’s” benefit. A disabled adult is entitled to SSDI benefits if one of his or her parents is currently receiving Social Security retirement or disability benefits or died after working long enough to qualify for some form of Social Security benefit. In addition, a “child” is eligible for SSDI benefits if he or she received dependent benefits on a parent’s Social Security earnings record prior to reaching the age of 18.

SSDI eligibility differs from SSI eligibility in that the recipient must meet the impairment definition for adults. The adult disability impairments include “autistic disorder and other pervasive developmental disorders.”

Finally the “child” must not be engaged any substantial work.

Education: The Individuals with Disabilities Education Act (IDEA)

IDEA is a federal law that mandates the availability of a Free Appropriate Public Education (FAPE) for all eligible children with disabilities. IDEA defines “disability” as a person “(1) with mental retardation, hearing impairments . . . speech or language impairments, visual impairments . . . serious emotional disturbance . . . orthopedic impairments, *autism*, traumatic brain injury, other health impairments, or specific learning disabilities . . . (2) who needs special education and related services because of his or her disability or disabilities” (IDEA § 802, emphasis supplied). Thus, children with ASD are eligible for IDEA-related services.

IDEA’s regulations define autism as “a developmental disability significantly affecting verbal and nonverbal communication and social interaction, generally evident before age three that adversely affects a child’s educational performance. Other characteristics often associated with autism are engagement in repetitive activities and stereotyped movements, resistance to environmental change or change in daily routines, and unusual responses to sensory experiences.”

A child with ASD is not eligible for IDEA-related services if the “child’s educational performance is adversely affected primarily because the child has an emotional disturbance.” An “emotional disturbance” is “a condition exhibiting one or more of the following characteristics over a long period of time and to a marked degree that adversely affects a child’s educational performance”:

- “An inability to learn that cannot be explained by intellectual, sensory, or health factors”
- “An inability to build or maintain satisfactory interpersonal relationships with peers and teachers”
- “Inappropriate types of behavior or feelings under normal circumstances”
- “A general pervasive mood of unhappiness or depression”

- “A tendency to develop physical symptoms or fears associated with personal or school problems”

IDEA’s regulations also classify schizophrenia as an emotional disturbance.

For those children diagnosed with ASD and not an emotional disturbance, Part C of the IDEA, Infants and Toddlers with Disabilities, provides for developmental services for children from birth to 3 years of age. Part B, Assistance for Education of All Children with Disabilities, mandates educational services for children from ages 3 to 21. The educational requirements of Part B include an individualized education program (IEP) for each child and demand the placement of each child in the least restrictive environment (LRE) possible.

An “appropriate” education must address a child’s specific educational needs. Determining what is appropriate entails several steps. The responsible state actor must conduct an individualized assessment to ascertain a student’s strengths and weaknesses. Next, an IEP team, comprising representative of the school district, a teacher, the child’s parents, and, if appropriate, the child, must identify appropriate goals and objectives for the student and construct an IEP designed to aid the student in meeting the goals and objectives. Finally, the IEP team is charged with identifying the aids and services necessary for the child to succeed in the IEP.

These services consist of “transportation and such developmental, corrective, and other supportive services as are required to assist a child with a disability to benefit from special education.” Specifically, they may include:

- Audiology
- Counseling services
- Early identification and assessment of disabilities in children
- Medical services for diagnosis or evaluation
- Occupational therapy
- Parent counseling and training
- Physical therapy

- Psychological services
- Recreation
- Rehabilitation counseling
- School health services
- Social work services
- Speech pathology
- Transportation

An IEP must include:

- “A statement of the child’s present levels of academic achievement and functional”
- “A statement of measurable annual goals including academic and functional”
- “A description of how the child’s progress toward meeting the annual goals will be measured”
- “A statement of the special education and related services and supplementary aids and services . . . to be provided”
- “An explanation of the extent, if any, to which the child will not participate with nondisabled children in the regular class and in extracurricular and other nonacademic activities”
- “A statement of any individual appropriate accommodations that are necessary to measure the academic achievement and functional performance of the child”
- “The projected date for the beginning of the services and program modifications and the anticipated frequency, location, and duration of those services and modifications”
- “Beginning not later than the first IEP to be in effect when the child is 16 and updated annually thereafter: appropriate measurable post-secondary goals”

IDEA conditions state receipt of federal funding on meeting its minimum requirements. States may not provide fewer services but may provide greater services.

The needs of children vary, and, as a result, children with ASD will be eligible for varying IEPs and services. Their needs and the services to which they are entitled will also likely change over time.

Antidiscrimination: The Americans with Disabilities Act (ADA)

The ADA prohibits discrimination on the basis of disability in employment, state and local governmental services, public accommodations, transportation, and telecommunications. A person is “disabled” if he or she has a physical or mental impairment that substantially limits one or more major life activities, has a history or record of impairment, or is perceived by others as having an impairment.

The ADA does not enumerate the impairments that are “substantially limiting,” leaving that question to the regulators and courts. In the decade and a half following the ADA’s enactment in 1990, the federal courts, including the United States Supreme Court, issued a number of decisions construing the statutory phrase very narrowly. This resulted in the denial of many ADA claims, including claims of those with ASD. In response, congress enacted the Americans with Disabilities Act Amendments Act of 2008 (ADAAA). The ADAAA’s central feature was a command that “the definition of disability in this Act shall be construed in favor of broad coverage of individuals under this Act, to the maximum extent permitted under the terms of the Act.”

Specifically, the ADAAA expanded the definition of “major life activities” by articulating a non-exhaustive list of the activities: “caring for oneself, performing manual tasks, seeing, hearing, eating, sleeping, walking, standing, lifting, bending, speaking, breathing, learning, reading, concentrating, thinking, communicating, and working.” In addition, the Act included “major bodily functions” within “major life activities” and presented a non-exhaustive list of these functions: “functions of the immune system, normal cell growth, digestive, bowel, bladder, neurological, brain, respiratory, circulatory, endocrine, and reproductive functions.”

The ADAAA also mandated that, with the exception of eyeglasses and contact lenses, the determination that impairment substantially limits a major life activity “be made without regard to the ameliorative effects of mitigating measures” such as medication and other “assistive

technology.” Most importantly for people with ASD, the determination must be made without regard to “learned behavioral or adaptive neurological modifications.” A temporary impairment, or one that is “episodic or in remission” qualifies as a disability even when inactive “if it would substantially limit a major life activity when active.” Examples would include posttraumatic stress disorder, epilepsy, or cancer.

On May 24, 2011, new regulations designed to implement the ADAAA and issued by the Equal Employment Opportunity Commission (EEOC), the agency charged with enforcing the ADA, went into effect. Echoing the ADAAA, the regulations provide that “[t]he definition of disability . . . shall be construed broadly, to the maximum extent permitted by the terms of the ADA.” More importantly, the regulations announce that the ADAAA shifts the focus of an ADA claim from whether a disability exists to “whether discrimination occurred.” Furthermore, the regulations provide that the question whether an individual is “substantially limited” in a major life activity “should not demand extensive analysis” and “usually will not require scientific, medical, or statistical analysis.”

Most importantly for those with ASD, the regulations provide the first explicit recognition that autism constitutes an ADA-recognized impairment. Indeed, Section 1630.2(j) (3) (iii) provides that “in virtually all cases,” a number of conditions, including autism, meet the definition of disability. According to the EEOC, “autism substantially limits brain function” and thus “will, at a minimum, substantially limit . . . major life activities.”

As a result of the ADAAA and its accompanying regulations, those diagnosed with ASD are assured eligibility for remedies should they experience discrimination in employment, governmental services, public transportation, public accommodations, or in telecommunications. In the employment context, the ADA prohibits discrimination in recruitment, hiring, promotions, training, pay, social activities, and other employment-related privileges. Governmental services include public education, employment,

transportation, recreation, health care, social services, courts, voting, and town meetings. Public transportation includes city busses, subways, trains, and the like. Public accommodations include businesses and nonprofit service providers that are open to the public. These enterprises include privately operated educational facilities, transportation services, and commercial facilities such as restaurants, retail stores, hotels, movie theaters, private schools, convention centers, doctors' offices, homeless shelters, transportation depots, zoos, funeral homes, day care centers, and recreation facilities including sports stadiums and fitness clubs.

Accommodations accorded those with ASD vary according to a person's impairments and the context. In the educational context (also covered by the Individuals with Disabilities Education Act (IDEA)), accommodations include special education teachers, teacher aides, more frequent feedback from teachers, and help with learning strategies or study skills. Other accommodations include the use of technological aids such as calculators, computer software, and audiobooks.

In the employment context, ASD-related accommodations include the articulation of clear job expectations, mandates that superiors and colleagues communicate in a direct manner, minimization of multitask assignments, and the use of instructional visuals.

Future Directions

Eligibility for private and public health insurance will be subject in the future to the fortunes of the Patient Protection and Affordable Care Act (PPACA). Eligibility for social security, educational, and antidiscrimination benefits will be subject to the priorities and directions of federal and state legislatures.

ELM Scale-2

► Early Language Milestone Scale

Elopement

Allan M. Andersen¹, Paul H. Lipkin^{2,3} and J. Kiely Law^{2,3}

¹Department of Psychiatry, University of Iowa, Iowa City, IA, USA

²Department of Medical Informatics, Kennedy Krieger Institute, Baltimore, MD, USA

³Department of Pediatrics, Johns Hopkins University School of Medicine, Baltimore, MD, USA

Definition

Elopement behavior, sometimes termed “wandering,” is defined as the leaving of a supervised, safe space by a dependent person, such as a person with Autism Spectrum Disorder (ASD). It refers to incidents lasting longer than a brief period of

running away, which is developmentally normal in toddlers but is rare in the typically developing population, particularly in those over 5 years of age (Anderson et al. 2012).

Historical Background

Historically, elopement was grouped with other “challenging behaviors” commonly encountered among individuals with ASD and/or Intellectual Disability (ID), such as aggressive and disruptive behavior, and received little specific attention (Dekker et al. 2002; Doehring et al. 2014; Matson and Nebel-Schwalm 2007; Matson and Rivet 2008; Murphy et al. 2005). The majority of research specifically focused on elopement behavior has been conducted on populations of individuals with dementia rather than ASD, potentially limiting applicability of findings to the ASD population (Algase et al. 2009; Cipriani et al. 2014; Lai and Arthur 2003).

Within ASD-related literature, the small body of published studies on elopement consist largely of case reports or small case series reporting on efforts to manage the problem using behavior analytic approaches, particularly Applied Behavioral Analysis (ABA), and the use of related interventions such as functional communication training, differential reinforcement of other behaviors, and noncontingent reinforcement (Call et al. 2011; Falcomata et al. 2010; Lang et al. 2010; Perrin et al. 2008; Piazza et al. 1997; Stevenson et al. 2016; Tarbox et al. 2003).

Current Knowledge

Interest in the problem of elopement has increased in the last decade as a result of increasing awareness of its potentially deadly consequences for individuals with ASD. High profile incidents including drownings and traffic accidents prompted calls for more research focused on understanding and preventing elopement (The Autism Wandering Awareness Alerts Response and Education (AWAARE) Collaboration; McIlwain and Fournier 2012). In parallel, research on the causes

of elevated mortality among individuals with ASD (Gillberg et al. 2010; Guan and Li 2017; Mouridsen 2013; Schendel et al. 2016), including one study documenting a 40-fold increased risk of drowning for these individuals, (Guan and Li 2017), pointed toward elopement as a potentially important modifiable risk factor for individuals with ASD.

Increased awareness of the risks of elopement and advocacy by parents and ASD organizations (McIlwain and Fournier 2010) led to the first large-scale study of elopement among individuals with ASD. Surveying over 1200 caregivers of children with ASD recruited via the Interactive Autism Network (IAN), an online research database and autism registry, Anderson and colleagues (2012) reported that 49% of children with ASD over the age of 4 had reported attempts of elopement at least once after the age of 4. Rates in children with ASD were dramatically higher than in their unaffected siblings, particularly among older children. Among survey respondents, 26% reported their children had been missing long enough to cause concern, with 24% of them reported in danger of drowning and 65% in danger of a traffic injury. Elopement risk was correlated with greater ASD severity, with an increased risk of 9% on average for each 10-point increase in Social Responsiveness Scale (SRS) T score. Families reported high levels of stress and lost opportunities to participate in activities outside the home due to elopement, yet only 50% of families reported receiving any advice or guidance on addressing the behavior. Unfortunately, as noted by the authors, the study was not able to provide an estimate on the number of fatalities specifically due to elopement due to inclusion of only living children with ASD.

Subsequent to the study of Anderson and colleagues, two other large-scale epidemiological studies published in 2016 provided population-based estimates of elopement prevalence and correlates of the behavior. Utilizing the Centers for Disease Control (CDC) "Pathways" Survey data, consisting of telephone survey responses from over 4000 parents of children with a developmental disability, including ASD and Intellectual Disability (ID) or Developmental Delay (DD), Rice

and colleagues (2016) reported on rates of elopement behavior occurring within the year prior to parental survey participation, with the highest rate (37.7%) seen among children with ASD and ID, followed by children with ASD but not ID (32.7%) and those with only ID (23.7%). Rice and colleagues also reported an elevated risk of elopement in male children with ASD versus female children with ASD (OR 2.79, CI 1.03–7.57; $P < 0.05$). Children with ASD and ID had the highest use of prevention measures for elopement (40.8%), compared with approximately 1 in 4 children with ASD without ID, or ID without ASD. However, Rice and colleagues noted that despite the high rate of use of prevention measures, details on the use of specific measures and their effectiveness were lacking, as was information on the circumstances and motivations for elopement in different individuals with ASD.

Analyzing the same CDC "Pathways" dataset, Kiely and colleagues (2016) reported that 26.7% of children with ASD, ID/Developmental Disability (DD), or both had eloped within the previous year, with the highest rates among children with ASD and ID (34.6%), followed by ASD only (32.7%) and ID/DD only (22.7%), consistent with the analysis of Rice and colleagues. Kiely and colleagues similarly found that greater ASD severity, as indicated by the Children's Social Behavior Questionnaire (CSBQ), was correlated with elopement behavior, consistent with the findings of Anderson and colleagues (2012).

Despite increasing awareness of the prevalence of EB and associated risks, little evidence has been available to guide families and caregivers in managing the behavior (McIlwain and Fournier 2010). Responding to this knowledge gap, advocacy organizations have provided resources for caregivers such as the National Autism Association's "Big Red Safety Toolkit" (National Autism Association 2014), which includes recommendations for preventative interventions such as door alarms, shoe ID tags, and visual prompts, as well as a recommendation for swimming lessons in order to reduce drowning risk.

At the same time, the use of tracking technologies such as GPS-enabled bracelets has continued to receive interest as a means of alerting

caregivers when individuals with ASD elope (Hayward et al. 2016). In particular, following the tragic 2013 death of Avonte Oquendo during an elopement incident, a 14-year-old boy from Queens, New York, with ASD, New York Senator Charles Schumer pledged federal funding for tracking devices, reflecting hope that widespread use of these devices could be an effective means of locating missing children. Despite this interest, adoption of tracking devices has been limited thus far, as reflected by Rice and colleagues who found only about 3% of parents using them (Rice et al. 2016), potentially due to associated costs as well as limited evidence on their effectiveness (Hayward et al. 2016).

Research into behavioral treatments for elopement also continues to be an area of active investigation, (Boyle et al. 2019; Leahy et al. 2013) with one recent study reporting a substantial reduction in elopement occurrences (Cohen's $d = 1.18$) in a sample of 11 subjects treated at an intensive day treatment clinic for an average of 37 sessions (Call et al. 2017). Overall, however, as reported in a 2017 review of functional analysis and function-based treatments for elopement by Boyle and colleagues (2017), the body of evidence supporting behavioral therapies for elopement is limited, with Boyle and colleagues finding only 12 studies totaling 20 subjects that met criteria for review and noting that "conclusions regarding effectiveness of treatments should be drawn tenuously." Boyle and colleagues noted inherent challenges in the study of elopement from a functional behavioral perspective, in particular that the consequences of the behavior are confounded by the requirement that the clinician retrieves the child before harm occurs and that the behavior itself may be infrequent and therefore unlikely to occur during the period of observation.

To address the knowledge gap in real-world effectiveness of interventions for elopement behavior such as those noted above, Andersen and colleagues (2019) reported on caregiver responses to elopement and elopement patterns, using a sample of over 500 caregivers of children with ASD recruited via IAN. Most respondents reported using multiple types of interventions to prevent elopement, finding this strategy in general

to be effective but burdensome. Tracking devices were used infrequently and not rated as highly effective, whereas some environmental interventions such as fencing and window locks were rated as highly effective. The use of behavioral specialists to address the behavior was also common and rated as effective. Given high rates of off-label psychotropic medication administration reported among individuals with ASD with challenging behaviors (Matson and Neal 2009), the frequency and effectiveness of medications used for elopement was also surveyed. Although off-label use of psychotropic medications to reduce elopement was reported by 16% of respondents, most commonly antipsychotics (29%), no medications were rated as effective in preventing the behavior, and most were associated with high rates of side effects.

In reporting on elopement patterns in this study, the most common locations for the behavior were the home (71%) and parks or outdoor spaces (49%). The most commonly associated motivations included anxious situations (43%) or running or exploring for enjoyment (41%). Similar to prior reports, the frequency of elopement behavior was associated with greater levels of ASD severity, as indicated by higher SRS scores, comorbid ID, Language Disorder (LD), and other challenging behaviors including aggression, self-injury, and disruptive behavior. Interestingly, children with ASD and comorbid ADHD were found to be significantly more likely to elope due to having "too much energy" ($P < 0.001$), whereas those with comorbid Anxiety Disorder, NOS were significantly more likely to elope from "stressful" environments ($P < 0.001$), supporting the hypothesis that motivations underlying elopement behavior vary and that different approaches to preventing the behavior may be required depending on the individual.

Future Directions

High priorities for preventing elopement and related injury or death include improving understanding of its causes and the identification of effective measures to prevent the behavior.

Significant advances have been made in the last decade in our understanding elopement's prevalence and correlates, while evidence on the relative effectiveness of different interventions for elopement remains significantly limited. Available research suggests that caregivers have responded to this lack of evidence by employing whatever measures are available to them to prevent their loved ones with ASD from suffering elopement-related death or injury, but that these efforts come at a substantial cost in terms of daily burden and stress.

Going forward, more effective tools to identify high risk individuals and prevent or respond to elopement among individuals with ASD are greatly needed. In addition, efforts to overcome barriers to implementing interventions that have some evidence of effectiveness such as fencing and window locks, may reduce the risks of injury and death among this population whose families already shoulder significant economic burdens associated with the disorder (Lavelle et al. 2014). Thankfully, with the addition of an ICD billing code for "wandering in diseases classified elsewhere" (Z91.83), reimbursement for elopement behavior in individuals with ASD, ID, and dementia may be possible, offering hope that families will be able to meet some of the expense associated with preventing and treating the behavior. Improved awareness of the prevalence and risks of elopement on the part of clinicians will also be essential in recognizing the behavior and offering families guidance and treatment strategies.

At the public health level, efforts to mobilize existing resources and develop new strategies to protect children who elope will continue to be high priorities. Community agencies such as local police departments and school districts should continue to work with families to identify individuals at high risk for elopement, develop preventative strategies, and respond appropriately when elopement occurs. Finally, continued efforts by organizations such as the National Autism Association (2014) and the National Center for Missing and Exploited Children (2019) to both provide families with resources on managing elopement and advocate for more research on

this important clinical problem will be essential to creating a future where these vulnerable individuals are safe from harm.

Embedded Figures Test (EFT)

Francesca Happé
MRC Social, Genetic and Developmental
Psychiatry Centre, Institute of Psychiatry,
Psychology and Neuroscience, King's College
London, London, UK

Description

The Embedded Figures Test (EFT) was designed by Witkin in 1971 to assess his concept of “field dependence – independence” (e.g., Witkin and Goodenough 1981). Good performance on the EFT was taken as a marker of field independence, the ability to disembed information from context

or surrounding gestalt. The test requires the participant to spot a simple form within a more complex figure; the color and form of the latter create a gestalt within which the part is hidden (see Fig. 1). In the Children's EFT, the complex figure is also meaningful (e.g., a pram, within which the triangle to be found is hidden in the hood). Group-administered and short versions are also available.

People with ASD are often extremely good at the EFT, as first demonstrated by Shah and Frith (1983). Fast and accurate performance on this test is thought to reflect the ability to see parts within wholes, to ignore the distracting effect of the gestalt, and to focus on details. Indeed, superior performance on the EFT (compared to age- and IQ-matched comparison group) was one of the first demonstrations of so-called weak central coherence in ASD and remains one of the best replicated findings (see Happé and Frith 2006 for review) (Fig. 2).

Embedded Figures Test (EFT), Fig. 1 The participant's task is to find the simple shape within the complex and camouflaging gestalt

Embedded Figures Test (EFT), Fig. 2 In the children's version of this task, the complex figure within which the target is hidden, is identifiable, adding meaning to the gestalt-to-be-ignored

Historical Background

Witkin (1916–1979) was a founder of the notion of cognitive and learning styles. He proposed the idea that personality could be measured in part by how people perceived their environment. In particular, he attempted to create objective tests (in contrast to questionnaire methods), such as the Rod-and-Frame test, to measure individual differences in reliance on external versus internal frames of reference. The Embedded Figures Test was created by Witkin as a more portable and convenient test designed to measure these same facets of field dependence or independence.

Shah and Frith (1983) were the first to use the Embedded Figures Test with individuals with autism, showing superiority compared to matched comparison groups. This was one of the key findings that led Uta Frith to propose her theory of “weak central coherence” in autism.

Emergency Department Utilization and Autism

Guodong Liu

Division of Health Services and Behavioral Research, Department of Public Health Sciences, The Pennsylvania State University, College of Medicine, Hershey, PA, USA

Definition

People with autism spectrum disorder (ASD) (American Psychiatric Association 2000) are susceptible to big emotional swings, and sometimes violent actions toward themselves and those around them, leading to frequent crises. Those with mental breakdowns and/or with acute, severe injuries often were often rushed to emergency departments (ED) for immediate treatments. Researchers have found a steady increase in ED visits by children and adolescents with ASD in the 2000s for both non-psychiatric and psychiatric referrals (McCraig and Burt 2005; Mahajan et al. 2009). This trend has also been documented more recently (Kalb et al. 2018; Liu et al. 2017, 2019) for adolescents and young adults with ASD who had higher documented ED visits compared to their same-age peers without ASD. Obsession with strict routines, stereotypy, self-injurious behavior (SIB) (Sterling et al. 2005), and plus deficits in social communication

make ASD patients prone to emotional instability ever since very early childhood. Physical maturation and the accompanying hormonal surge, among other triggers of various nature, further amplify the adverse consequence from those outbursts among young ASD patients. In addition, other mental and physical health comorbidities coupled with core ASD deficits which create barriers to accessing health care services for individuals with ASD often make those with ASD prone to acute adverse health events requiring treatment in the emergency department (ED) (Liu et al. 2019). These mental and physical comorbidities also lead to high rates of healthcare utilization and contribute to a growing cost for healthcare needs for children and adolescents with ASD. In fact, overall cost of medical care is greater for children with ASD compared to children without ASD (Croen et al. 2006; Leslie and Martin 2007; Peacock et al. 2012).

Historical Background

Non-psychiatric and psychiatric referrals have been increasing at a higher rate when compared to individuals without ASD (McCraig and Burt 2005; Gurney et al. 2006; Mahajan et al. 2009; Liu et al. 2017; Kalb et al. 2018). Deavenport-Saman et al. (2016) found that children and adolescents with ASD had 0.26 more documented visits to the ED when compared to individuals without ASD and that older children with ASD (i.e., school-age compared to preschool-age) were utilizing the ED more. A recent examination of ED utilization in adults with ASD found a similar trend in high utilization of the ED (Nicoliadis et al. 2013). Middle to late adolescence and residing in rural areas appeared to reflect higher rates of ED utilization in comparison to early adolescence and residing in urban areas. In addition, higher ED utilization was observed in females as compared to males with ASD, as well as a significant increase in behavioral health visits in the ED over time. Adolescents with ASD do not appear to be adequately supported through the transition to adulthood as they experience more social and communication difficulties often while dealing

with new-onset mental health conditions. This may be particularly true for older youth, those residing in rural settings, and for adolescent females with ASD.

Current Knowledge

Population Vulnerability

ASD patients typically have deficits in social communication, sensory sensitivities, stereotypical and self-injurious behaviors (SIB), as well as other well-known ASD signature behaviors. These ASD hallmark characteristics contribute to emotional dysregulation for ASD patients starting in early childhood (Samson et al. 2014) and consequently subject them more susceptible to emotional breakdown and physical injuries that often need emergency medical attentions, such as visits to emergency departments. Stereotypy refers to repetitive but typically not goal-directed behaviors (Sterling et al. 2005). Some stereotypical behaviors even not appear to be violent, are often associated with SIB. For example, reparative licking often cause skin damages. Young ASD children seldom cause server bodily-damage to themselves. In contrast, it was often acute flaring of lingering medical problems that leads them to ED.

There have been reports that those with have lingering comorbid physical health concerns, such as epilepsy (Tuchman and Cuccaro 2011; Berg and Plioplys 2012) and gastrointestinal (GI) illnesses (Chaidez et al. 2014; Dinan and Cryan 2017) which often lead to increased ED utilization. In addition, medical conditions such as respiratory problems (Kohane et al. 2012; Ming et al. 2016) and other miscellaneous injuries (Jain et al. 2014; Summers et al. 2017) have high prevalence of ED utilization among people diagnosed with ASD. A majority of children and adolescents with ASD are also diagnosed with multiple comorbid diagnoses, including anxiety, depression, and disruptive behavior disorders (Gotham et al. 2015; Gordon-Lipkin et al. 2018). For some children with ASD, physical maturation and the accompanying hormonal changes in adolescence, among other stressors associated with

adolescence, amplify the adverse consequence from depleted coping abilities among young ASD patients as they grow to face up the rules, disciplines, as well as social pressures from peers as well as teachers and school administrators at schools, even parents at home. The transition to adolescence is a particularly stressful time for individuals with ASD and their caregivers as social and societal demands increase, physical and sexual maturity advances, and parental emotional stress often peaks.

Another vulnerability faced by those with ASD is polypharmacy, generally defined as medications prescribed to individuals which are simultaneously filled across two or more classes of medications (Spencer et al. 2013). Given that the majority of children and adolescents with ASD present with comorbid mental and physical health issues, it is not uncommon for physicians to prescribe multiple medications both within and across drug classes, even though the majority of this practice is “off-label.” In particular, prescription of psychotropic medications, especially multiple medications often put those with ASD in great danger of having acute adverse events, often leading to visits to the emergency departments.

Many of the medical conditions among those with ASD may not require care in the ED if managed properly with adequate and regular access to health care services. As with psychiatric care, there are likely several barriers to routine healthcare, management of chronic health concerns, and accessing urgent care for adolescents with ASD. These barriers may include lack of access to health care services, socioeconomic barriers, deficits in communication and social interaction skills, distress or fear responses particularly in novel settings, and sensory sensitivities related to the healthcare setting (Gurney et al. 2006). Additionally, families who have children with ASD are also more likely to experience unmet health care needs, more likely to delay or forgo health care, and more likely to report a high dissatisfaction with care (Kogan et al. 2008; Chiri and Warfield 2012). Taken together, these barriers may contribute to a higher utilization of the ED to identify and manage acute healthcare needs in adolescents with autism.

Non-psychiatric and Psychiatric ED Visits

There has been a steady increase in utilization of the ED for both non-psychiatric and psychiatric referrals by children and adolescents over time (McCraig and Burt 2005; Mahajan et al. 2009). This trend has also been documented in children and adolescents with ASD and has been found to be increasing at a higher rate when compared to individuals without ASD (Gurney et al. 2006).

The most common non-psychiatric problems presenting at ED visits include epilepsy seizures and/or neurological symptoms (9–15%); gastrointestinal disturbances (15%) such as nausea, vomiting, diarrhea, abdominal pain, and constipation (Tuchman et al. 2010; Cohen-Silver et al. 2014; Deavenport-Saman et al. 2016); upper respiratory infections (7%) and viral infections (7%); otitis media (5%); and head or dental injuries (7%) (Deavenport-Saman et al. 2016). Epilepsy has been long found to be highly comorbid with ASD. Studies reported a pooled ASD prevalence of 6.3% among those with epilepsy and prevalence of epilepsy among those with ASD range from 2.7% to 44.4% (Bolton et al. 2011), while the prevalence of epilepsy in the general population is only approximately 0.5–2% (Nguyen and Tellez Zenteno 2009). GI problems has been widely studied and reported in association with ASD, despite the fact that a causal link between these two remains to be established (Chaidez et al. 2014; Dinan and Cryan 2017). Nevertheless, the prevalence of various GI issues has been reported ranging anywhere from 23% to 70% (Chaidez et al. 2014).

As ASD children grow up, those who visited ED more often involve mental health emergencies. While psychiatric-related ED visits have been found to be increasing at a swifter rate than non-psychiatric reasons for referral to the ED (Liu et al. 2017). It is reported that psychiatric-related ED visits among ASD patients have out-paced those of non-ASD population; most recently during year 2013 with about 20% of all ED visits among ages 12–21 years, ASD patients involve psychiatric/behavior health service (Liu et al. 2017). Kalb et al. (2012) found that ED visits for children and adolescents with ASD were more likely to be related to a psychiatric concern than

non-psychiatric concern. In regard to common psychiatric reasons for referral to the ED, Iannuzzi et al. (2014) found that as children with ASD entered elementary, school behavioral issues became a common reason for referral to the ED. However, around the time of entry into middle school, in addition to behavioral issues, mood symptoms, self-injurious behavior, and more significant aggression entered into the top reasons for referral to the ED and remained stable into young adulthood. Wharff et al. (2011) found that children with developmental disabilities, including ASD, were 2.5 times more likely to utilize the ED while waiting for an opening on a psychiatric inpatient facility.

Approximately one-fourth of children and adolescents with ASD have been found to make repeated visits to the ED, and of this 25%, half of the individuals had been to the ED in the 2 weeks prior to the current visit (Cohen-Silver et al. 2014). Of the children and adolescents with ASD who present to the ED, almost 20% have been subsequently admitted to the hospital compared to a rate of 10% in children and adolescents without ASD (Cohen-Silver et al. 2014). Deavenport-Saman et al. (2016) found that children and adolescents with ASD were less likely to be admitted to the hospital from the ED if they arrived at the ED during weekday daytime or evening hours, were female, were English-speaking, and had no insurance. In the same sample, being 6 years old or older, being non-Hispanic, and traveling a greater distance to the ED led to high admittance rates.

Risk Factor and Predictors of ED Visits

A variety of factors, acting independently, or interacting with each other, contribute to the mental and/or physical crises among young ASD patients, leading to higher ED utilization. It is known that a wide spectrum of ASD patients may have different comorbid mental illnesses. Kalb et al. (2012) reported that externalizing mental health illnesses were associated with ED visits and subsequent hospitalizations. On the other hand, Liu et al. (2017, 2019) found that female

adolescents and young adults with more internalizing comorbid illnesses, such as anxiety disorders, mood disorders, and depression, were more likely to visit ED compared to those with comorbid externalizing mental health diagnoses (e.g., ADHD, ODD, psychosis). Females with ASD are more often to have comorbid internalizing disorders but are less likely to be referred to the specialists for assessment than males ((Rucklidge 2010). However, if left undiagnosed, or undertreated, symptoms of these illnesses may exacerbate to the level of level of crises and medical emergencies and ED visits.

Entering high school (age 12–14) and exiting high school (age 18–21), times of transition often put tremendous pressure on female adolescents and young adults with ASD because often during which when new social relationships are to be established and new skills mastered. They struggle with establishing and maintaining appropriate peer relationships (Holtmann et al. 2007). This new layer of difficulty is particularly distressing for female adolescents with ASD as they may have had some success with peers when younger due to shared interests which cannot be sustained secondary to growing social communication deficits (Van Wijngaarden-Cremers et al. 2014).

Many researchers have proposed that increased ED utilization for children and adolescents with ASD may be related to deficits in first-line, community-based, outpatient care (Green et al. 2001; Leichtman et al. 2001). Caregivers of typically developing children and adolescents who reported that their PCP stresses family centeredness, timeliness, and coordinated care have been found to report decreased numbers of visits to the ED (Brousseau et al. 2009). Similarly, caregivers of children and adolescents with ASD report they are more likely to access the ED for healthcare when they perceived their healthcare providers do not listen to their concerns, display cultural insensitivity, do not supply needed information, and do not involve caregivers in decision-making. Therefore, it is less likely that caregivers of youth with ASD access their PCPs for routine visits that are for minor issues as a result of having less assurance for help with acute, emergent,

and/or complex behavioral or health issues (Kogan et al. 2008).

Finally, those living in rural areas have been found to have less access to regular and specialty medical and mental healthcare and therefore may be more likely to present at the ED for mental healthcare. Approximately half of families of children with ASD living in a rural community reported that they experienced problems with the services they received, most often as a result of lack of availability of well-trained providers. Caregivers of individuals with ASD living outside of metropolitan centers in Australia noted a lack of ASD expertise in healthcare providers in rural and remote areas of the country. Thomas and colleagues found that caregivers of children with ASD who lived in rural communities in the United States reported significantly less access to special summer camps and respite care. Another indicator of a paucity of services in rural communities is the documented older mean age of diagnosis of ASD for individuals living in a rural community when compared to those in suburban or urban settings (Mandell et al. 2005). Recent research has begun to examine the efficacy of telehealth remote technology, group-based parent interventions, and training models for PCPs to meet the needs of individuals with ASD and their families in rural settings.

Future Directions

Not only are ASD youth utilizing the ED at disproportionate rates, they are accessing the ED for behavioral health concerns at increasing rates outpacing non-ASD youth. By 2013, over 20% of ASD youth were accessing ED services for a readily identified behavioral health concern (Liu et al. 2017, 2019; Kalb et al. 2018). This appears to be a significant factor as the changes in behavioral health presenting concerns mirror the overall increased ED utilization. Adolescents with ASD who present for emergent psychiatric care appear to have difficulty accessing community-based mental health services. Children and adolescents with ASD have been documented as having significant difficulty accessing specialty medical and

mental health care when compared with other youth with disability. Better access to behavioral health services designed for adolescents with ASD, such as social skills training and specialized care coordination, appears to be a critical need. Greater understanding of service utilization before and after ED visits for youth with ASD is needed to craft more impactful interventions for individuals at risk.

Definition

Emergent literacy refers to the many literacy-rich activities children participate in prior to formal reading and writing instruction from birth to about 5 years of age. Specifically, emergent literacy has been defined as “the reading and writing behaviors of young children before they become readers and writers in the conventional sense” (Justice 2006, p. 3). Examples of emergent literacy activities include engaging in shared storybook reading, pretending to write or draw, incorporating literacy themes into play, and engaging in oral wordplay such as rhyming. Shared storybook reading is arguably the most common emergent literacy activity for many children. Parents read to children who are very young before they can verbally participate. Parents often engage in scaffolding or supportive behaviors during emergent literacy activities. Through scaffolding, parents adapt the experience to match the child’s growing abilities, thus supporting the child’s participation. For typically developing

children, emergent literacy instruction is most effective when it is targeted authentically instead of during contrived instructional “skill and drill” activities (Price and Ruscher 2006). Emergent literacy is associated with later literacy achievement and the development of other important skills. For example, children who experience more high-quality reading experiences early in childhood have larger vocabularies than children with fewer experiences (see Temple and Snow 2003 for a review). Emergent literacy activities provide a rich context for learning and practicing joint attention skills, which are particularly vulnerable in children with autism spectrum disorders. Historically, emergent literacy activities were withheld from some children who did not demonstrate signs of readiness, including oral language abilities and behavioral precursors. However, there is no evidence to suggest that any child should be excluded from emergent literacy activities. Because children with autism spectrum disorders are at risk for reduced opportunity for literacy achievement, providing rich and diverse emergent literacy activities is one way to support the literacy access for this population.

Emergent Literacy Skills of Preschoolers with Autism

Synonyms

Early literacy; Reading

Definition

Emergent literacy is the stage of reading development that precedes conventional reading. Children are in the emergent literacy stage from birth to about 6 years old. During this stage, children are being exposed to experiences that will increase their knowledge and abilities in emergent literacy skills. Emergent literacy skills include alphabet knowledge, print-concept knowledge, phonological awareness, and narrative skills. For children who are typically developing, researchers have found that emergent literacy skills are strong predictors of later success with reading. There is an emerging body of research on emergent literacy and its role in the acquisition of conventional literacy skills for children with autism. Several common findings have emerged across the literature. First, as a group, children with autism tend to have a discrepant profile of strengths in code-related skills (i.e., alphabet knowledge) but meaning-related skills that seem to lag behind their peers. However, there is significant variance in emergent literacy skills for children with autism. The heterogeneity in emergent literacy has been found to be related to autism severity, oral language, and non-verbal cognition.

Definition

The Emotion Awareness and Skills Enhancement (EASE) Program is an individual therapy

intervention that was designed to improve emotion regulation skills and overall well-being in adolescents and adults with autism spectrum disorder (ASD).

Historical Background

Many people with ASD have interfering problems with emotional and behavioral control that lead to the use of psychiatric services including therapy, medications, and even inpatient hospitalization. Intense and sudden negative reactions, anxiety and worry, aggression and hostility, and persistently high negative affect are some examples of these emotional and behavioral problems, which are unfortunately very common in ASD, substantially impede capacity to learn and function across all life settings, and affect quality of life for the affected individual and family members. Despite the prevalence of emotional and behavioral concerns in ASD and widespread use of psychiatric services to address these concerns, there are few treatments that impact these behavioral and emotional concerns in ASD with proven effectiveness.

Psychotherapeutic intervention approaches in ASD have predominantly focused on the use of cognitive-behavioral therapy (CBT). Although applied primarily to anxiety in ASD, CBT has been proven effective for a range of concerns in non-ASD populations (Epp and Dobson 2010). CBT is considered an effective treatment for co-occurring anxiety in individuals with ASD who do not have intellectual disability (Shaker-Naeeni et al. 2014). However, CBT protocols for ASD have been developed primarily to treat specific anxiety disorders and, as such, generally do not address many common problems such as explosive behavior, irritability, and depression. In addition, not all individuals respond to CBT, and the improvements tend to be less substantial than observed in non-ASD populations (Kreslins et al. 2015). Given the multiple co-occurring problems seen in this population and concerns about applicability of CBT, a more efficient, and perhaps effective, approach is to target the core processes underlying the clinical phenomena.

Treatments that target a process that is believed to be shared or common across multiple disorders or problems are often referred to as transdiagnostic treatments. Transdiagnostic treatment models appear to be at least as effective as well-established, disorder-specific treatments in reducing symptomatic impairment (in non-ASD samples) (e.g., Barlow et al. 2010). They also have the advantage of not requiring therapists to be familiar with different treatment manuals for every specific disorder and are easier to apply to youth with complex presentations (e.g., youth who present with multiple types of concerns). The possibility that transdiagnostic approaches may have wider application than disorder-specific treatments suggests that these approaches could promote broader dissemination and adoption.

Emotion regulation is a strong candidate to target as a transdiagnostic treatment in ASD. Emotion regulation involves the modulation of arousal and emotional state to promote goal-directed behavior (Thompson 1991). Emotion regulation impairment may underlie many of the social, behavioral, and emotional problems presented by individuals with ASD (Mazefsky et al. 2012, 2013). Individuals with ASD may fail to employ adaptive emotion regulation strategies and instead react impulsively to emotional stimuli, with aggression, extreme social withdrawal, or self-injury (Sofronoff et al. 2007). Such behaviors are often interpreted as deliberate or defiant but may be more accurately understood as reduced capacity to manage emotional states. Furthermore, emotion regulation impairment is thought to underlie internalizing problems in non-ASD populations (Aldao et al. 2010), and it is quite likely that emotion regulation impairment plays a role in the commonly observed anxiety (White et al. 2009), suicidal behavior (Maddox et al. 2017), irritability, and depression (Magnuson and Constantino 2011) in ASD as well. This would suggest that successful treatment of emotion regulation impairment may produce improvement across many different manifestations of emotion regulation impairment in individuals with ASD.

The best approach to address emotion regulation in ASD may include mindfulness.

Mindfulness, taken from Buddhist tradition and defined in a multitude of ways, generally focuses on meditative and present-moment and nonjudgmental awareness of thoughts, emotions, and actions (Baer 2003). These techniques have been integrated into existing therapies, such as CBT, and into the development of new therapies in which mindfulness principles are the primary focus, such as mindfulness-based cognitive therapy (MBCT; Baer 2003). Additionally, mindfulness-based interventions have been tailored toward clinical, community, health, and nonclinical populations for the improvement of symptoms such as anxiety, depression, anger, overall well-being and quality of life, and stress, among other outcomes (see Gotink et al. 2015, for review).

Therefore, the development of EASE was based on existing theories and approaches related to both mindfulness-based and CBT interventions. Dr. Carla Mazefsky, Dr. Susan White, Dr. Kelly Beck, and Dr. Caitlin Conner jointly drafted a new intervention manual, called Emotion Awareness and Skills Enhancement (EASE), in order to apply a blend of these strategies in a manner that would be most effective for ASD. EASE was refined through an iterative process that involved input from key stakeholders, including individuals with ASD, parents of individuals with ASD, and clinicians.

Rationale or Underlying Theory

EASE is based on the premise that many of the behavioral and emotional problems experienced by individuals with ASD result from impaired emotion regulation. Although informed by effective interventions for emotion regulation in non-ASD populations, EASE was developed to address ASD-specific obstacles to effective emotion regulation (see Mazefsky et al. 2013; Mazefsky and White 2014). One of the primary considerations is that individuals with ASD often “react to emotional stimuli intensely without clear goal-directedness...and this may be compounded by poor emotional insight and self-monitoring” (Mazefsky et al. 2013, pp. 683–684). Individuals

with ASD without co-occurring Intellectual Disability also report greater use of less adaptive emotion regulation strategies such as suppression and resignation, which function to avoid emotion and generally tend to be ineffective at reducing distress (e.g., Jahromi et al. 2012; Weiss 2014). Therefore, EASE attempts to address these obstacles with a mindfulness-based approach in which awareness of emotion is cultivated, emotions (whether negative or positive) are acknowledged, and behavior is regulated in the face of intense emotion with mindfulness and/or cognitive strategies.

EASE uses both “bottom-up” [mindful awareness] strategies (e.g., emotion cuing, present awareness), which primarily address affective under-control, cognitive rigidity, and poor insight, and “top-down” strategies drawn from CBT (e.g., cognitive reframing, skills practice).

Given that emotion regulation impairment often manifests in the context of social situations in individuals with ASD, EASE’s treatment targets are addressed therapeutically in social situations. In other words, the social milieu is embedded in the treatment. For example, in learning about how to build tolerance for distress, the youth might practice this first in session with just the therapist and then gradually use the skills in increasingly social settings (e.g., with parents, then at school). Additionally, EASE frequently requires evocation of the emotion regulation impairment in the context of treatment. Social interaction may be used, therefore, to evoke difficulty as well as practice skills.

Goals and Objectives

The overall goal of EASE is to develop skills which allow the individual to manage distress and act in ways that are more adaptive (i.e., goal-consistent) rather than avoiding or reducing the experience of negative emotion. EASE has three primary treatment targets:

(1) Mindfulness and emotion awareness – This includes noticing emotions and body sensations and building the ability to identify changes in emotional intensity by learning the physical cues of intensifying emotions.

(2) Recognition of when emotion becomes dysregulated – This includes understanding the relationship between thoughts, feelings, sensations, and behaviors, as well as identifying the influence on and effect of social challenges.

(3) Providing “tools to calm the chaos” – This includes building tolerance for distress and practicing different strategies for emotion management (which is referred to as “ABCD”: awareness, breathe, change thoughts, temporary distraction).

Treatment Participants

EASE was developed for adolescents and adults who are cognitively able and verbal (i.e., no presence of intellectual disability and verbal IQ of at least 80), because of the cognitive and verbal demands of the therapy. An adaptation of EASE for individuals with ASD and co-occurring Intellectual Disability (EASE-ID) is currently in development. EASE is for individuals who have emotion regulation impairment of any type. This could include problems with depression, anxiety, anger, frustration tolerance, general stress management, or frequent outbursts/meltdowns. It was developed specifically to address the challenges and learning style of individuals with ASD, and thus far EASE has only been applied to individuals with ASD. However, the approaches and content of EASE likely also apply to other populations characterized by emotion regulation impairment. For example, while EASE was developed for individual outpatient therapy settings, a group-based school version of EASE which will include any student with emotion regulation impairment (not solely students with ASD) is also in development.

Treatment Procedures

The EASE program includes 16 50–60-minute sessions over the course of approximately 16 weeks. The treatment is delivered individually by a therapist and supported by parent involvement and online content. Each session begins with a mindful

check-in, review of the weekly practice, agenda setting, skill teaching, skill practice, a mindfulness exercise, and planning for post-session practice. Parents are brought into each session before the mindfulness practice and homework assignment.

There is an online platform to support EASE called emotionCoach or “eCoach.” eCoach is available to both the youth and parent. The hope is that having materials from session, as well as additional information to support the concepts introduced in session, available online at any time will allow individuals to learn and process information at their own pace. The parent is encouraged to use eCoach to learn strategies alongside the child. eCoach includes written summaries of the content for each session, all handouts used during EASE, written mindfulness exercises from EASE, and an audio recording of each mindfulness exercise. There are also some additional tips and frequently asked questions on eCoach. Families are encouraged to preview material on eCoach ahead of sessions if they wish. Ideally, parents are asked to review the eCoach content while their child is in session, to aid synchronous learning.

A key treatment component of EASE involves community sessions that were designed to provide an opportunity to practice the skills being learned in a more natural environment. Community sessions are structured so as to evoke sufficient emotion/distress in the client and support from the therapist for use of regulatory skills while distressed. Inclusion of the community sessions reinforces learning of new skills and improves generalization outside of the clinic. Often the community sessions literally involve leaving the office and going somewhere where social and environmental challenges will be more likely to naturally occur. Based on feedback from families, we believe these sessions are most impactful when they can take place in situations that are highly challenging and relevant to the client’s daily life.

Efficacy Information

Primary data on EASE is from an open trial, indicating that they are feasible, acceptable, and

can be administered to fidelity across sites (Conner et al. 2019). Over 70% of the participants were treatment-responders via clinician-naïve report. Parent report of emotion regulation impairment, irritability/aggression, anxiety, and depression symptoms decreased during treatment with medium-large effect sizes (Conner et al. 2019). An ongoing randomized controlled trial, comparing participants who receive EASE to those who receive an individual supportive therapy, will provide more information on efficacy (ClinicalTrials.gov: NCT03432832).

Outcome Measurement

EASE was developed to improve overall emotional reactivity and regulation as measured by the Emotion Dysregulation Inventory (Mazefsky et al. 2018a, b). Secondary outcomes include changes in specific problematic symptoms such as depression, anxiety, or aggression.

Qualifications of Treatment Providers

EASE therapists should have a background in a field that provides mental health intervention services (clinical psychology, advanced education degrees, rehabilitating sciences, social work, etc.). Therapists who participated in the initial trial of EASE included those with the following backgrounds: clinical psychology doctoral students, licensed psychologists (PsyD and PhD), licensed professional counselor, and master of education. EASE therapists ideally should have some prior experience working with clients with ASD and some familiarity with mindfulness-based interventions and cognitive-behavioral therapy. It is recommended that new EASE therapists receive supervision of their first EASE case and ongoing group supervision or consultation thereafter. EASE includes a variety of recommended readings on emotion regulation in ASD and mindfulness approaches.

Definition

Children's emotion regulation capabilities are strategies that are used to manage (inhibit, enhance, or maintain) emotional experiences (Thompson 1994) and develop within the context of social interactions. Parents facilitate the advancement of their children's emotion regulation through *emotion coregulation* processes. Conceptually, emotion coregulation involves transactional exchanges between parent-child dyads; however, there is a lack of consensus regarding the optimal definition of emotion coregulation. Numerous related terms and definitions have been used to describe dyadic emotion processes between parents and their children. For example, synchrony refers to parents and children matching their behaviors and affect states to regulate emotional arousal (Feldman 2003); parent-driven coregulation involves behaviors that parents engage in to motivate or scaffold children's emotion regulation strategies (Gulsrud et al. 2010; Ting and Weiss 2017), and shared affect describes matched emotion expression between parents and children. In our program of research (Guo et al. 2017a; Valentovich et al.

2018), emotion coregulation is defined as a dynamic process of mutual construction of affective states and regulation of arousal between parents and children (see also Butler and Randall 2013; Tronick 1989).

Emotion coregulation with parents provides children the foundation for the development of their own emotion regulation capabilities. The ability to self-regulate emotional states and behavioral actions begins to emerge in infancy and continues to develop throughout childhood through interactions with important others (Kopp 1982, 1989), with parent-child interactions playing a critical role. During the early years, children's growing self-regulation capabilities require additional support to manage emotional arousal. Parents demonstrate emotion regulation strategies and provide external regulation for young children (Kopp 1989). Children initially depend on their parents to assist in modulating their emotional experiences (e.g., parent physically soothes child by holding her) given young children's limited self-regulation skills. During social interactions, parents and children jointly regulate their emotional experiences through emotion coregulation (Cole et al. 2004; Feldman 2003). Repeated dyadic interactions allow for children to practice effective emotion regulation strategies and for parents to facilitate (e.g., scaffold) children's strategies. As children become older, they gain a wider range of emotion regulation strategies and learn to increasingly rely on their own self-regulation strategies (Calkins and Hill 2007; Kopp 1989).

An important aspect to consider when studying emotion coregulation is the emotional content of parent-child interactions. The emotional content of dyadic interactions, which may include mutual positivity, mutual negativity, or mismatched emotion engagement (e.g., child in negative state and mother in positive state), has been the focus of many studies on neurotypical (NT) children and children with behavioral problems. For example, one study examined parent-NT child shared emotion expression during a semi-structured play activity and children's behavioral outcomes (Lindsey et al. 2013). Results showed that mutual positivity between

these young children and their mothers predicted fewer aggressive behaviors with peers, whereas mutual negativity predicted more aggressive behaviors with peers 8 months later. For parents and their children with behavioral problems, the emotional content of emotion coregulation differs from those of NT dyads. In one study, mother-child dyads of preschool-aged children with behavior problems engaged in more mutual negativity and mismatched emotion engagements relative to dyads of NT children (Cole et al. 2003). Increased mutual positivity and decreased mutual negativity in dyads over time were also found to be related to improvements in behavioral problems. These findings suggest that emotional content is an important aspect of emotion coregulation and children's adaptive functioning. It may be particularly important to include a focus on emotional content when examining emotion coregulation processes in children with developmental challenges.

Emotion coregulation processes between parents and their children with developmental disorders, such as Autism Spectrum Disorder (ASD), require unique consideration. Children with ASD have deficits in social interactions that impact parent-child social exchanges, such as a tendency to focus on objects and impaired joint attention on a shared task (American Psychiatric Association 2015; Dawson et al. 2004). Moreover, children with ASD tend to have impaired emotion regulation capabilities. The role that parents of children with ASD have with respect to teaching key emotion regulation strategies may be particularly challenging, as these children tend to lack adaptive emotion regulation strategies and may instead react with intense emotional responses and poor emotional control (Mazefsky et al. 2013). Children with ASD may not respond to parents' attempts at effective coregulation strategies in a manner analogous to NT children. Thus it is important to gain insight into early emotion coregulation processes between parents and their children with ASD as children are developing their self-regulation abilities. Such knowledge may in turn inform parent-child interventions targeting children's emotion regulation and adaptive functioning.

Historical Background

ASD is a lifelong, neurodevelopmental disorder that is characterized by challenges in social communication and restricted, repetitive behaviors (American Psychiatric Association 2015). In addition to core symptoms, children with ASD also commonly exhibit impairments in behavioral and emotional functioning. Prevalence rates for at least one co-occurring behavioral problem, such as internalizing symptoms (e.g., anxiety and depression) or externalizing symptoms (e.g., aggression and impulsivity), range from approximately 70% to 86% for children with ASD (Chandler et al. 2016; Ooi et al. 2011; Simonoff et al. 2008). Children with ASD also tend to have difficulties with aspects of emotional functioning, such as emotion expression, recognition, and regulation (Konstantareas and Stewart 2006; Uljarevic and Hamilton 2013). Importantly, impairments in children's ability to regulate their reactions to emotionally arousing situations may represent one key factor in the mechanisms that underlie the behavioral problems that children with ASD display (Mazefsky and White 2014).

The ability to regulate emotional experiences across contexts is a significant goal in early child development and is associated with concurrent and overall adaptive functioning (Denham et al. 2003; Eisenberg et al. 1993). Effective emotion regulation strategies (e.g., problem-solving and cognitive reappraisal) are linked to adaptive functioning, whereas ineffective strategies (e.g., physical aggression and avoidance) are associated with a host of emotional, behavioral, and social problems throughout the life span (Aldao et al. 2010; Southam-Gerow and Kendall 2002). Prior research on the emotional challenges that children with ASD face has primarily focused on children's emotion expression and recognition (e.g., Rump et al. 2009; Sasson 2006; Yirmiya et al. 1989); findings show difficulties in both domains. Over the past two decades, emotion regulation in children with ASD has begun to receive more attention (Cai et al. 2018; Mazefsky et al. 2013). Although the body of work investigating emotion regulation capabilities of children with ASD is relatively small, such work

represents important advances in our understanding of emotional functioning in children with ASD.

Research on emotion regulation has examined diagnostic group differences between children with ASD and NT children as well as the relationship between emotion regulation and socioemotional and behavioral outcomes in children with ASD. Overall, children with ASD have greater impairments in emotion processes relative to their NT peers. Specifically, in terms of emotion regulation skills, studies using various methodologies, including behavioral observations, child reports, and parent reports, have demonstrated that children and adolescents with ASD use more ineffective strategies and fewer effective strategies than NT peers across a variety of contexts (e.g., positive and negative situations) (Jahromi et al. 2012; Konstantareas and Stewart 2006; Samson et al. 2015). For example, observations of children during frustrating tasks demonstrated that preschool- and school-aged children with ASD used fewer efficient strategies (e.g., distraction) and more maladaptive strategies (e.g., physical objection) compared to NT peers (Jahromi et al. 2012; Konstantareas and Stewart 2006). Similarly, another study using parent report found that relative to NT peers, school-aged children and adolescents with ASD engaged in increased maladaptive strategies (e.g., repetitive behaviors) and decreased adaptive emotion regulation strategies (e.g., cognitive reappraisal) across positive and negative emotion states (Samson et al. 2015). Moreover, these children were less effective at utilizing strategies such as problem-solving, social support, and distraction.

In addition to the increased challenges that children with ASD encounter in regulating their emotional experiences relative to NT peers, emotional difficulties are also associated with socioemotional and behavioral problems. For example, in one study, parent ratings of emotion regulation skills of their preschool-aged children with ASD were related to children's socioemotional functioning, such that ineffective emotion regulation was associated with decreases in social skills and increases in internalizing and externalizing behaviors 10 months later

(Berkovits et al. 2017). Similarly, in another study, 9- to 12-year-old children with ASD who self-reported using maladaptive emotion regulation strategies, such as self-blame, also had higher levels of depressive symptoms and anxiety (Rieffe et al. 2011).

For children with ASD, early parent-child relationships may be particularly important for the development of efficient emotion self-regulation and for improving maladaptive behaviors. However, parent-child relationships within the context of emotion coregulation have only recently been explored in a handful of empirical studies (e.g., Gulsrud et al. 2010; Hirschler-Guttenberg et al. 2015a; Ting and Weiss 2017). Additionally, fathers are less often included in such research relative to mothers, and few studies have investigated emotion coregulation processes between fathers and their children with ASD (e.g., Hirschler-Guttenberg et al. 2015b). Prior studies on NT dyads suggest that fathers play an important role in children's socioemotional development (e.g., Cabrera et al. 2007; Lindsey et al. 2013). The inclusion of fathers in research on emotion coregulation in dyads of children with ASD may be important in order to expand our understanding of their unique contribution to the development of children's emotion regulation capabilities and adaptive functioning.

Prior work has demonstrated the importance of emotion coregulation, yet our understanding of these dyadic emotion processes for children with ASD and how they relate to their functioning is limited. Thus, the objectives of our program of research were to (a) compare patterns of emotion coregulation in mother-child dyads of children with ASD and NT children (Guo et al. 2017a), (b) examine associations between aspects of emotion coregulation and children's behavioral functioning in mother-child dyads of children with and without ASD (Valentovich et al. 2018), and (c) investigate emotion coregulation processes and children's behavioral functioning in father-child dyads of children with ASD (Guo et al. 2017b). Grounded in dynamic systems theory, our studies used a novel application of the State Space Grid (SSG) method (Lewis et al. 1999), a dyadic micro-level approach, to analyze

parent-child emotion engagements during a semi-structured play activity at home. Advantages of using a dyadic micro-level method are that parent and child behaviors can be analyzed simultaneously, rather than individually, and that momentary shifts between parent-child behaviors and affect states, rather than global behaviors, can be captured.

Current Knowledge

Past and current research indicates that parents shape children's emotion regulation capabilities during dyadic social exchanges by modeling appropriate behaviors, providing emotional coaching (e.g., labeling and validating emotions), teaching specific regulation strategies (e.g., redirecting attention and complex cognitive strategies), and monitoring and responding to children's cues, among others (Morris et al. 2007; Thompson and Meyer 2007). Parents of children with and without ASD engage in similar types of emotion coregulation behaviors; however, they differ in the frequency of behaviors. Parents of children with ASD, for example, use more direct, active strategies (e.g., redirecting and prompting) and engage in more physical behaviors (e.g., physical soothing) relative to parents of NT children (Doussard-Roosevelt et al. 2003; Gulsrud et al. 2010; Hirschler-Guttenberg et al. 2015b). Parents of children with ASD are sensitive to children's cues, and the differences in the frequency of specific strategies used may suggest an awareness of the child's developmental needs. Additionally, parent emotion coregulation behaviors are associated with behavioral outcomes for children with ASD. For example, greater parental scaffolding (e.g., sensitive responses to child) during discussions of negative past events between parents and their school-aged children with ASD was found to be associated with fewer child externalizing behaviors (Ting and Weiss 2017).

Recently, the SSG approach, based on dynamic systems theory, has provided a unique method for examining emotion coregulation in parent-child dyads. The SSG has been used to analyze fine-grained parent and child emotion processes

simultaneously to capture the transactional nature of dyadic interactions, rather than a global examination (Hollenstein 2007; Hollenstein and Lewis 2006). Moreover, the SSG allows for operationalizing emotion coregulation in terms of emotional content and structure of dyadic interactions. Emotional content refers to the ability of dyads to initiate and maintain emotion engagement (i.e., mutual positive, mutual negative, or mismatched interactions). Structure refers to the emotional variability of interactions (i.e., the range of emotional interactions, the shifts of emotions, and perseveration in an emotion state) (Granic et al. 2007; Hollenstein et al. 2004).

Research utilizing the SSG has demonstrated that both the emotional content and structure of emotion coregulation are associated with children's behavioral outcomes. For example, Hollenstein et al. (2004) analyzed interactions between parents and their high-risk children during a series of activities, including discussions of problems that cause conflict. Results indicated that decreased dyadic emotional variability (structure) when children were in kindergarten predicted higher levels of children's externalizing behaviors in first grade. Lunkenheimer et al. (2011) assessed parent-child emotion coregulation in a challenging block design task at home when children were 3 years old. The results showed that the interaction between dyadic parent-child emotional variability (structure) and positive affect predicted lower externalizing problems in children at age 5.5 years.

This method previously has been used to examine dyads of NT children and children with behavioral problems. Our lab is the first to use the SSG to examine emotion coregulation processes in families raising children with ASD (Guo et al. 2017a; Valentovich et al. 2018). In our recent studies, the emotional content and structure of emotion coregulation were examined in dyads of children with ASD and dyads of NT children utilizing the SSG approach. Mothers and their preschool-aged children completed the Three Boxes procedure (Tamis-LeMonda et al. 2004; Vandell 1979), a 10-min semi-structured play activity, in their home. During the activity, mothers and their children were given three

numbered boxes that contained toys, and mothers were asked to open the boxes in sequential order. This procedure reflects activities that mothers and their children typically engage in and reliably elicits maternal and child behaviors. Play sessions were videotaped for later coding of emotion engagement states of mothers and children. Children's internalizing and externalizing behaviors were also assessed using mother-reported Vineland Adaptive Behavior Scales (Sparrow et al. 2005) scores.

A novel coding scheme was developed to capture emotion engagements, which were predicated on behaviors, body postures, attention, facial expressions, and vocalizations, in both families of NT children and children with ASD. Mothers and children were coded separately for low, medium, and high levels of positive engagement, negative engagement, and disengagement states; children were also coded for object engagement (for detailed information on the coding schemes, see Guo et al. 2017a). Mangold International's INTERACT 9.47 (Mangold 2007) software program was used to code engagement states in 5-second intervals. The separate codes were merged for each dyad to create dyadic engagement states: *mutual positive engagement* (mother and child in any positive engagement state), *mutual negative engagement* (mother and child in any negative engagement or disengagement state), *mismatched engagement* (mother in any negative engagement or disengagement state and child in any positive engagement state; mother in any positive engagement state and child in any negative engagement or disengagement state), and *child-object* (mother in any engagement state and child in object engagement). The dyadic engagement codes were exported to the SSG software (State Space Grid GridWare 1.1.; Lamey et al. 2004) to obtain the emotional content (i.e., initiating and sustaining dyadic engagement states) and the structure (i.e., range of emotional interactions, the shifts of emotions, and perseveration in an emotion state) of the interactions.

The first goal of our research was to compare the emotional structure and content of interactions between mother-child dyads of children with ASD and dyads of NT children (Guo et al.

2017a). Results indicated that in terms of the structure, dyads of children with ASD engaged in greater emotional variability (i.e., a wider range of emotional interactions, greater shifts of emotions, and less time spent in an emotion state) relative to dyads of NT children. In terms of emotional content, dyads of children with ASD initiated mutual positive, mismatched, and child-object engagements more frequently and spent more time in mismatched and child-object engagements relative to NT dyads, whereas dyads of NT children spent more time in mutual positive engagements relative to dyads of children with ASD. Results suggest that high emotional variability in a low-stress context may not imply adaptive interactions for children with ASD but rather suggests difficulty maintaining positive interactions with their mothers.

The second goal of our research was to investigate whether interactions between emotional variability (structure) and mutual positive/negative engagements (content) of emotion coregulation were associated with maladaptive behaviors in children with ASD (Valentovich et al. 2018). Results indicated that for dyads of children with ASD, greater emotional variability (structure) and more frequent initiation of mutual positive engagements (but not negative engagements) were associated with fewer maladaptive behaviors (i.e., internalizing and externalizing behaviors) for children with ASD. These findings suggest that both flexible interactions and shared positive interactions may play an important role in preventing behavioral problems in children with ASD.

New research by Guo, Goldberg, Valentovich, and Garfin includes fathers and their children with and without ASD in research designed to parallel the mother-child studies. Semi-structured play activities were videotaped and later coded for father and child emotion engagement states using the coding schemes described above. Fathers also completed the Vineland Adaptive Behavior Scales (Sparrow et al. 2005) to assess their children's adaptive and maladaptive behaviors. This is the first study to examine the association between emotion coregulation in father-child dyads of children with ASD and children's

adaptive functioning utilizing the SSG method (Guo et al. 2017b). In general, we found that more time spent in positive engagements (content) and less time spent in mutual negative engagement (content) were associated with higher levels of adaptive behaviors in children with ASD. These results point to the importance of father-child positive interactions in social and emotional development in children with ASD.

Future Directions

Studies conducted to date on aspects of emotion coregulation between parents and their children with ASD demonstrate its importance for children's adaptive functioning; however, this area of inquiry is underresearched. Several key areas should be considered in future studies.

Emotion Coregulation Across Contexts

In our research, parents and their children were observed during a low-stress play task. The type of play (e.g., toy play, physically orientated play) that parents and children engage in as well as different emotion-eliciting contexts (e.g., low stress vs. high stress) may impact the process of emotion coregulation (Hirschler-Guttenberg et al. 2015b; Jahromi et al. 2012; Warreyn et al. 2005). For example, in past research, mothers' emotional availability toward their children with ASD varied across free play, structured play, and social play contexts (Dolev et al. 2009). In a mildly frustrating context, children with ASD used a greater range of emotion regulation strategies but were less effective compared to NT children (Konstantareas and Stewart 2006). Hirschler-Guttenberg and colleagues (2015b) showed that children with ASD displayed more negative emotions and behaviors with fathers in a fearful context, but not in a joyful context compared to NT peers. Although children with ASD are more vulnerable to negative emotional states, more studies are needed to clarify how both parents and children respond to different social contexts (Mazefsky et al. 2012). Furthermore, additional research should examine how emotion coregulation processes will unfold in terms of both

emotional structure and content when parent-child behaviors are observed in contexts other than play, such as during high-stress tasks.

Longitudinal Design

Much of the research on emotion coregulation to date has been cross-sectional. Age effects of emotion regulation on developmental outcomes would be removed in a longitudinal design. Future work with a longitudinal study design would help clarify relationships between emotion coregulation and developmental outcomes in children with ASD. In this way, a mechanism of emotion coregulation for psychiatric comorbidity and social competencies in children with ASD would be better understood (Mazefsky et al. 2013). Specifically, future research could expand emotion coregulation to include not only micro-real-time measurement but also context-to-context emotional variability and developmental changes as described in Hollenstein's Flex3 model (Hollenstein 2015).

Dyadic Repair

Disruptions that affect positive parent-child interactions occur routinely but can be managed by a process of dyadic repair (Beeghly and Tronick 2011). The ability of parents and children to repair ruptures, or to recover from temporarily mismatched or negative interactions by returning to positive states, could be crucial for children's adaptive functioning (Beeghly and Tronick 2011; DiCorcia and Tronick 2011). For example, NT preschool-aged children who engaged in higher rates of repair processes with their mothers during a challenging puzzle task also demonstrated the ability to use appropriate regulation strategies and had fewer externalizing behaviors 4 months later (Kemp et al. 2016). Ruptures in positive interactions and attempts to repair such interactions may provide an opportunity for children to internalize efficient strategies for managing challenges and learn that they do not need to remain in negative situations (Tronick and Beeghly 2011). Future work should examine repair processes in dyads of children with ASD across low- and high-stress contexts (e.g., free play in the home environment

vs. challenging laboratory task) as well as explore how dyadic repair processes are related to children's adaptive functioning.

Clinical Implications

Past research has emphasized the negative aspects of emotion regulation among children with ASD. Our studies expand prior findings by demonstrating that dyads of parents and their children with ASD can initiate positive interactions, but they have a diminished capacity for sustaining positive interactions relative to NT dyads in a low-stress, home environment. These results could guide future family-systems-based interventions that focus on improving the ability of parent-child dyads to maintain longer positive interactions, which may be particularly important for families raising children with ASD. In particular, children may benefit from interventions that focus on helping parents assist their children in engaging in dyadic positive interactions to reduce children's behavioral problems and improve adaptive functioning. Recent studies have generated evidence that a variety of techniques could plausibly be used to extend positive interactions in dyads with children with ASD; these include mentalization-based interventions (Slade 2005), relational savoring interventions (Burkhart et al. 2015), and mindfulness-based interventions (Cachia et al. 2016). From our research, we recommend that future studies incorporate micro-analytic indicators of different aspects of emotion coregulation when evaluating the effects of interventions.

Emotion Dysregulation Inventory

Carla A. Mazefsky

Department of Psychiatry, School of Medicine,
University of Pittsburgh, Pittsburgh, PA, USA

EDI

Description

The Emotion Dysregulation Inventory (EDI) is an informant questionnaire that assesses poor emotion regulation and is validated for general community and clinical populations as well as youth with autism spectrum disorder (ASD). It was created using methods developed by the Patient-Reported Outcomes Measurement Information

System (PROMIS®). The EDI items were developed based on an iterative process that included caregiver input. The EDI response options ask respondents to rate each item on a 5-point Likert scale from “not at all” to “very severe” for observed functioning over the past 7 days. Caregivers of 1755 youth with ASD completed 66 candidate EDI items, and the final 30 items were selected based on classical test theory and item response theory (IRT) analyses. The analyses identified two factors: (1) Reactivity, characterized by intense, rapidly escalating, sustained, and poorly modulated negative emotional reactions, and (2) Dysphoria, characterized by anhedonia, sadness, and nervousness. The final items did not show differential item functioning (DIF) based on gender, age, intellectual ability, or verbal ability. Because the final items were calibrated using IRT, even a small number of items offers high precision, minimizing respondent burden. IRT co-calibration of the EDI with other commonly used measures demonstrated its superiority in assessing the severity of emotion dysregulation with as few as seven items. Validity of the EDI was supported by expert review, its association with related constructs (e.g., anxiety and depression symptoms, aggression), and higher scores in psychiatric inpatients with ASD compared to a community ASD sample. Analyses in a general sample of 1000 youth matched to the US Census on age, gender, race/ethnicity, years of education, and region supported the EDI’s original factor structure and psychometrics, including its sensitivity, reliability, and validity. The general youth sample data was also used to generate normative cutoffs to determine clinical significance. In sum, the EDI provides an efficient and sensitive method to measure emotion dysregulation for clinical assessment, monitoring, and research in individuals of any level of cognitive or verbal ability across populations.

The EDI is available for use (requests can be made at: www.reaact.pitt.edu by completing the “EDI Inquiry Form”). The EDI is available in English, Spanish, French, Dutch, German, Danish, traditional Chinese, and Turkish. Requests for other translations can be made through the inquiry form. Theta score and t-score conversions are

available based on either the autism norms or general population norms. Examples of Reactivity items include: “Has explosive outbursts,” “Has trouble calming him/herself down,” “Emotions go from 0 to 100 instantly,” and “Cries or stays angry for 5 minutes or longer.” Examples of Dysphoria items include: “Very little makes him/her happy,” “Seems sad or unhappy,” “Not responsive to praise or good things happening,” and “Refuses to leave the house or go to school unless forced.”

Historical Background

Emotion dysregulation, or difficulty modulating emotion in the service of one’s goals, is common in individuals with ASD and has significant implications for treatment needs and outcome (Mazefsky 2015; Weiss et al. 2017). However, the lack of sensitive measures suitable for use across the range of functioning in autism spectrum disorder (ASD) is a barrier to treatment development and monitoring. Most emotion regulation measures were developed for the general population and excluded youth with ASD when assessing their psychometric properties. In addition, emotion regulation measures generally rely on self-report or use wording such as “complains about” or “worries about,” which limits their utility for youth with minimal verbal ability. Having a dimensional measure of emotion dysregulation that could be applied across the autism spectrum would enable a more complete understanding of the role of emotion dysregulation in ASD and facilitate treatment planning and monitoring.

The EDI was developed to meet this need. As such, it was designed to capture the full range of manifestations of poor emotion regulation in ASD. Another primary goal was for it to be applicable across the autism spectrum, with items that could be rated regardless of the individual’s verbal ability. Therefore, the emphasis is on observable signs of poor emotion regulation, and the format is informant questionnaire. Informant report is an ideal form of assessment in situations when the individual is unable to report due to cognitive or other limitations, making it an appropriate method for assessing minimally verbal youth with ASD.

In addition, informant perspectives on emotion dysregulation are important because limited emotional insight and awareness is common in ASD (Griffin et al. 2016).

The EDI was created using guidelines from an NIH Roadmap Initiative focused on developing sensitive outcome measures, PROMIS® (www.nihpromis.org). The multiple-site PROMIS Research Network (2012) produced scientific standards for developing measures as well as a comprehensive battery of effective and sensitive outcome measures. The EDI was the first measure for ASD developed based on PROMIS principles.

The EDI item development process was described in detail in Mazefsky et al. (2018a). First, a comprehensive review of emotion regulation and existing measures of related constructs was completed to inform development of a conceptual model. The conceptual model was structured with a primary domain (emotion dysregulation), subdomains (affective experience and affective control), factors (negative mood, anxiety, reactivity, and emotional inflexibility), and facets (increased negative affect, decreased positive affect, disturbed behavior, decreased vitality, nervousness and fear, hyperarousal, rapid escalation, intensity, lability, sustained reactions, and poor modulation of emotion). The actual dimensional structure was tested empirically at a later step, but the conceptual model structure was utilized to develop an item hierarchy, which involved assignment of draft items to each facet to ensure adequate coverage of key constructs. The draft of items was reviewed by experts in ASD and measure development.

Once the initial item pool was developed, interviews were completed with 19 parents of children and adults with ASD who varied in verbal and intellectual ability and age to assess their understanding of the items and their decision-making processes when selecting their responses. Information generated from these interviews, along with input from a panel of experts in measure development and emotion dysregulation in ASD, was utilized to revise the items, directions, and response options and arrive at the final 66 candidate items that were used for psychometric analyses and calibration.

The complete EDI item bank, directions, and response options had a Flesch Reading Ease of 66.3 (scale of 0–100 with higher scores indicating easier to read) and a Flesch-Kincaid Grade Level of 7.6, which are both considered adequate. Without the instructions, which include some longer passages with guidance on how to interpret behavior, the items and response options had a Flesch Reading Ease of 100 and a Flesch-Kincaid Grade Level of 2.1.

Psychometric Data

The complete psychometrics of the EDI in an ASD sample are described in Mazefsky, Yu, White, Siegel, and Palkonis (2018b). The EDI psychometrics were established utilizing a sample that was representative of the full spectrum of severity of ASD (Interactive Autism Network; IAN) while also being enriched with the most extreme forms of emotion dysregulation in ASD (Autism Inpatient Collection; AIC). IAN uses the Social Communication Questionnaire Lifetime for confirmation of parental report of professional diagnosis of ASD. Parental report of professional diagnosis of ASD has been verified by medical records. A prior study documented the validity of the ASD diagnoses in IAN through standardized clinical assessments and independent clinician verification (see Lee et al. 2010 for full details). The AIC is a six-site study of children, adolescents, and young adults admitted to specialized inpatient psychiatric units for youth with ASD and other developmental disorders. The full methods of the AIC have been published previously (Siegel et al. 2015). Participants in the AIC had ASD confirmed by the Autism Diagnostic Observation Schedule-2 and expert opinion.

A total of 1755 caregivers of children with ASD from IAN ($n = 1323$) and AIC ($n = 432$) combined completed the EDI for psychometric analysis. The mean age in both samples was 12 with a standard deviation of 3, though the range for IAN's sample was 6–17.9, whereas the range for the AIC was 4–20. In the combined sample, 27.8% had intellectual disability, 55.3% were fluently verbal, and 20.9% were female. The

AIC had a higher proportion of youth with intellectual disability and limited verbal ability, and the gender composition was equal in both sources. The proportion of the combined sample with co-occurring intellectual disability and percent female was consistent with national autism surveillance statistics (Baio et al. 2018).

First, the dimensionality of the EDI item bank was explored. In order to do so, the sample was split in half for exploratory factor analysis (EFA) and confirmatory factor analysis (CFA). Given differences in IQ and verbal ability for the IAN and AIC samples, EFA was performed separately, as well as for the combined sample. The eigenvalues and factor structures were similar across the three samples; therefore, the combined sample was used for all additional analysis. The 1- and 2-factor solutions emerged as the most meaningful, given the scree plots, the magnitude of eigenvalues, and clinical interpretation. In the combined sample, the eigenvalues were 29.48 and 4.71 for the first two factors. Factor 1 was characterized by items capturing rapidly escalating, intense, and labile negative affect as well as difficulty downregulating that affect (sustained reactions and trouble calming down). Factor 2 included items that reflect common definitions of general negative affect (sadness, unease, and anxiety) as well as low motivation or anhedonia. The second round of EFA on the combined sample retained 53 items with the same general content, there were no items that loaded >0.45 loading on both factors, and the correlation between the two factors was 0.51.

Next, single-factor CFAs were completed on the reduced item pool, using the second half of the sample ($n = 885$). For F1, all factor loadings were greater than 0.50, and several fit indices were uniformly strong: RMSEA = 0.09, CFI = 0.96, TLI = 0.96. For F2, all factor loadings were larger than 0.45, and fit indices revealed less homogeneity in CFA terms (reflected primarily in a larger RMSEA: RMSEA = 0.12, CFI = 0.86, TLI = 0.84).

Based on the EFA and CFA analyses, the original 66 items were trimmed to a pool of 53 items distributed across two factors (Reactivity and Dysphoria). Next, the two corresponding item banks were calibrated separately using two-

parameter graded item response theory response model (GRM) for polytomous items (i.e., items with three or more ordinal response categories). The items were individually evaluated based on their slope parameter which measures item discrimination (i.e., how well the item differentiates higher versus lower levels of severity or Θ in IRT terms). Useful items have larger slope parameters. In addition, threshold parameters which measure item difficulty (i.e., the ease versus difficulty of endorsing different response options for an item) were explored. Local dependency (i.e., residual correlations) in the IRT models was also assessed using the LD chi-square. Finally, item analyses included investigation of differential item functioning (DIF) by gender, age, verbal ability, and IQ flagged no items by both DIF methods, and no further items were eliminated for this reason. Item information curves were also examined to eliminate items with limited information, i.e., less than 0.50.

Thus, the final calibrated item bank after completing all of these steps included 30 items: 24 items for factor 1 (Reactivity) and 6 items for factor 2 (Dysphoria). Overall, Reactivity was more robust than Dysphoria, with more items, better IRT parameters, and smaller standard errors. For example, 20 items had item information values over 2.0 for Reactivity, with the following items all having total item information values over 3.0: has explosive outbursts, hard to calm him/her down when mad or upset, has extreme or intense emotional reactions, has trouble calming him/herself down, has emotions go from 0 to 100 instantly, and cries or stays angry for 5 min or longer. For Dysphoria, only three items had item information values over 2.0, and only “very little makes him/her happy” had an item information value over 3.0. The correlation between the two EDI factors was 0.63 in the combined sample, 0.50 for AIC, and 0.59 for IAN, all significant at $p < 0.001$.

To be able to provide a static short form for Reactivity, items were rank ordered on four criteria: discrimination parameters, the percentage of times the item would have been selected in a simulated CAT using the calibration sample, expected information under the standard normal

distribution with a mean of 0 and SD of 1, and expected information under a normal distribution with a larger SD, i.e., a mean of 0 and SD of 1.5. Seven items were selected for the short form based on the convergence of the four psychometric criteria, the content of candidate items, and location parameters. The theta correlation between the short form and the full bank was 0.98.

Next, concurrent calibration, which refers to estimating item parameters across multiple measures on a single computer run, was completed to evaluate how well the EDI captures variability in emotion dysregulation in comparison to other measures. The EDI was compared to the Aberrant Behavior Checklist Irritability Scale (ABC-I; 15 items), Child Behavior Checklist (CBCL) Stress Problems Scale (14 items), and an Emotion Dysregulation Index from the CBCL (CBCL-EDI) that included 18 items that experts in emotion regulation agreed captured the construct (Samson et al. 2014). The full EDI Reactivity scale (24 items) provided more than double the test information than any other comparison measure. The EDI Reactivity Short Form, with just seven items, also provided about the same amount of information as the ABC-I and more information than the CBCL-EDI and CBCL-SPS across the same range of theta (-2 to $+2$ SDs).

Initial evidence for construct validity was based on expert review (see Mazefsky et al. 2018a). In addition, correlations with legacy measures revealed expected patterns. In particular, both EDI factors (Reactivity and Dysphoria) were positively and moderately to strongly correlated with measures of similar constructs [(CBCL Stress Problems; $r(1754) = 0.562, p < 0.001$) and Samson CBCL-Emotion Dysregulation Index; $r(1754) = 0.748, p < 0.001$]. In addition, they were correlated as expected with scores for other behavioral and emotional problems, based on prior literature demonstrating an association between emotion regulation and these constructs. Finally, the AIC group had significantly higher EDI Reactivity (mean = 0.91, SD = 0.80) and EDI Dysphoria theta scores (mean = 0.55, SD = 0.83) than the IAN sample (EDI Reactivity: mean = -0.30 , SD = 0.85, $t = 25.8, df = 1753, p < 0.001$; EDI Dysphoria: mean = -0.18 ,

SD = 0.87, $t = 15.4, df = 1753, p < 0.001$), as well as a higher proportion of the sample with items rated as moderate or higher. These findings suggest that EDI scores differ in expected ways between known groups, in support of criterion validity.

The EDI's psychometrics were also established in a general sample of youth in order to enable its use across populations and to generate clinical cutoffs (Mazefsky et al. 2020). The sample included parents of 1000 6- to 17-year-old youth, matched to the US Census on gender, age, race/ethnicity, years of education, and region. The sample was recruited through YouGov, a global public opinion polling company. Confirmatory factor analyses were conducted to determine whether the two-factor structure of the EDI derived in the autism sample still held. Because the highest response options (severe and very severe) were endorsed less frequently in the YouGov sample, IRT was also completed with these response options combined to determine if that would yield any benefit, in addition to completing IRT analyses with the original five response options. The same methods utilized to generate the EDI Reactivity Short Form were completed again, to evaluate whether the same or different items should be used in the short form for more general use outside of ASD. IRT co-calibration was completed to compare the EDI to existing measures of related constructs, as described previously in the autism sample. Finally, validity was assessed by examining the EDI's correlations with measures of related constructs, comparing means between groups that would be expected to differ, and receiver operating characteristics which provide an index of sensitivity to identify different groups.

The results in the general US sample provided strong support for the EDI and were consistent with conclusions from the prior work in the autism clinical sample. The factor structure with separate Reactivity and Dysphoria scores was upheld, with strong evidence for unidimensionality (factor loadings from 0.72 to 0.91 and strong fit statistics). Reactivity and Dysphoria were correlated 0.71, $p < 0.001$. IRT results with four versus five response options were roughly equivalent, so the five response option

version was retained to maintain consistency with the earlier autism work. The IRT parameters were strong and comparable to the original IRT parameters in the autism sample (slope parameters ranging from 2.13 to 3.62 for Reactivity and from 1.81 to 3.64 for Dysphoria). Seven items had slope parameters above 3.0 for Reactivity and three had slope parameters above 3.0 for Dysphoria. The reliable range of measurement was -0.75 to $+4$ SDs for Reactivity and 0 to $+3.75$ SDs for Dysphoria. The computerized adaptive testing results to identify the best short form items resulted in six of the same seven original items; so the full short form was retained as originally developed for consistency. Even with fewer items, both EDI scales provided more information, across a wider range of severity, than all existing measures of related constructs that were compared via IRT co-calibration. Both Reactivity and Dysphoria were correlated as expected with existing measures, in support of concurrent validity. Finally, EDI scores were significantly higher for both Reactivity and Dysphoria scales for those who had been psychiatrically hospitalized, who had a crisis evaluation within the past 2 months, who were taking psychotropic medications or in therapy, and who had current psychiatric diagnoses, all $p < 0.001$. These findings were consistent with the results of the receiver operating characteristics.

Clinical Uses

The EDI has strong evidence to support its use in ASD, as well as general community and clinical samples. Overall, it has enhanced precision compared to previously existing measures, and it is brief and efficient. It may be useful for screening in initial clinical assessments as well as progress and outcome monitoring. The EDI provides norms both based on an autism sample and based on a general sample of youth, with clinical cutoff guidelines based on the general population norms. The autism norms may be most useful in situations when clients or samples include more severe forms of emotion dysregulation. The most psychometric evidence is for youth aged 6–17.9.

Several projects are underway to develop a self-report version for adolescents and adults, norms for informant report for adults, and an informant report for 2- to 5-year-old children.

one's emotions to fit the context or meet one's goals" (Thompson 1994). We all carry a toolbox of strategies to regulate our emotions (Calkins 1994; John and Gross 2007), which can be driven by ourselves, or driven by others, and can be active or passive (Gross 1998; Gyurak and Etkin 2014). Children with autism spectrum disorder (ASD) often have difficulty with regulating their emotions, which has been found to impact their behavioral and mental health. An emerging field of research has documented the strategies that children with ASD use to regulate their emotion and how these strategies overlap and differ from their typically developing peers across ages. Of particular importance is the emergence of emotion regulation strategies early in life.

Definition

At the core of mental health and well-being lies the ability to manage negative emotions. Emotion regulation is “the processes related to modifying

Historical Background

Emotion regulation skills have been shown to predict school success (Graziano et al. 2007; Gumora and Arsenio 2002; Howse et al. 2003), and conversely, difficulties with emotion regulation predict problem behavior and mental health problems (Eisenberg et al. 2000, 2001; Graziano et al. 2007; Hill et al. 2006; Rubin et al. 1995; Silk et al. 2003). Children with ASD are at a higher risk for episodes of emotional dysregulation, compared to their typically developing peers (Mazefsky et al. 2013; Samson et al. 2014); one study showed 74% of children with ASD have emotion regulation difficulties compared to 18% of typically developing children and 42% of children with intellectual disability (Totsika et al. 2011).

The features of emotional dysregulation in children with ASD include emotional lability (Samson et al. 2012), negative mood and irritability (Samson et al. 2014; Zwaigenbaum et al. 2005), internalizing symptoms such as anxiety and depression (Berthoz and Hill 2005), and externalizing behaviors, such as aggression and hyperactivity (Ashburner et al. 2010; Bauminger et al. 2010). Common ASD symptoms have been found to be associated with poorer emotional regulation (Mazefsky et al. 2013), including sensory abnormalities and restricted/repetitive behaviors

(Samson et al. 2014), social/communication deficits (Pouw et al. 2013a), and executive function difficulties (Jahromi et al. 2013). Additionally, as emotion regulation skills are built upon foundational joint attention (Morales et al. 2005; Raver 1996) and language (Cohen and Mendez 2009; Gallagher 1999; Gottman 1986) skills, individuals with ASD are significantly disadvantaged in their ability to deploy emotion regulation compared to typically developing peers due to significant difficulties in these core areas of ASD. The developmental trajectory of emotion co-regulation to self-driven regulation is built on a foundation of emotional expression (to signal the need for regulation), and here too, individuals with ASD are at a disadvantage due to difficulty unambiguously expressing emotional states and in identifying and describing their own emotions (Berthoz and Hill 2005; Nuske et al. 2013; Samson et al. 2012).

Most of the research to date examining emotion regulation strategies in individuals with ASD has focused on adolescents or adults, finding increased use of maladaptive forms of emotion regulation, including rumination, shutting down, suppression (with later outbursts), blaming others, avoidance, isolation, self-harm, and use of drugs (Bruggink et al. 2016; Mazefsky et al. 2014; Patel et al. 2017; Samson et al. 2012, 2015a, b; Santomauro et al. 2017). Findings also suggest less success with adaptative strategies, such as problem-solving and cognitive reappraisal (Bruggink et al. 2016; Samson et al. 2015b), along with successful use of other strategies including special interests, relaxation, music listening, and online communities (e.g., gaming communities; Santomauro et al. 2017).

Numerous research groups have found that maladaptive or avoidant strategies in adolescents and adults with ASD are associated with higher depression, anxiety and problem behavior, and lower well-being and social functioning (Bruggink et al. 2016; Cai et al. 2019; Goldsmith and Kelley 2018; e.g. Khor et al. 2014; Patel et al. 2017; Pouw et al. 2013b; Rieffe et al. 2011; Samson et al. 2015a).

Less work has focused on the emotion regulation strategies of children with ASD, though

initial findings are consistent with the adolescent and adult data. For example, Rieffe et al. (2011) found that some strategies, such as positive coping, may be less effective for 9- to 12-year-old children with ASD compared to typically developing children. Emotion dysregulation is particularly troublesome in school settings (Ashburner et al. 2008), where problem behaviors, which have been causally linked to maladaptive emotion regulation (Samson et al. 2015a), have been found to directly predict teacher burnout (Hastings and Bham 2003; Hastings and Brown 2002). Interestingly, Konstantareas and Stewart (2006) found 3- to 10-year-old children with ASD used a greater range of strategies than typically developing children, suggesting a trial-and-error (vs. social learning) approach, which is more common in ASD than in typical development (Vivanti et al. 2016; Vivanti and Rogers 2014).

Current Knowledge

In particular, studying emotion regulation strategies during the preschooler period is of great interest as this may help to identify key intervention targets in children who generally have easier access to 1:1 intervention, prior to school entry. Emotion regulation difficulties start early in children with ASD; by 12 months, 86% of parents of children with ASD reported regulatory difficulties (Gomez and Baird 2005). By preschooler age, typically developing children use multiple strategies that may be classified as co-regulated via others/other-directed (e.g., social negotiation, hugs) vs. self-directed (e.g., self-talk, self-soothing, deep exhalation) and passive (e.g., gaze aversion, task disengagement) vs. active (e.g., leaving one task for another) (Buss and Goldsmith 1998; Grolnick et al. 1996; Kopp 1989). There is also a shift from regulating through caregivers to regulating through other adults, such as teachers or even unfamiliar adults (Zimmer-Gembeck and Skinner 2011). Therefore, the typical emotion regulation strategy trajectory for preschoolers is shaped by parallel developments in autonomy and growing awareness of one's agency.

The few studies that have focused on emotion regulation strategies in preschoolers with ASD show that findings from the older population are already in place by this age, with increased maladaptive strategies, such more avoidance, resignation, and venting or tension release (Gulsrud et al. 2010; Jahromi et al. 2012; Zantinge et al. 2017). Results by Zantinge et al. (2017) found that use of such strategies was related to language impairments in the preschoolers with ASD, suggesting that developmental delays are driving the use of less optimal strategies relative to their typically developing peers. Consistent with this interpretation, Nuske et al. (2017) found that preschoolers with ASD used strategies that are characteristic of younger typically developing children, such as reliance on their family members for physical and communicative soothing, whereas the typically developing children relied on people outside of their family for help regulating their emotion. Moreover, authors found that positive self-development (self-recognition, self-evaluation, and autonomy) was related to more adaptive emotion regulation strategies in the preschoolers with ASD (Nuske et al. 2017).

Findings by Jahromi et al. (2012) suggest the pattern of less effective employment of strategies that are adaptive in typically developing individuals is also present in preschoolers with ASD; they found social support strategies (orienting and verbalizing to the experimenter) were ineffective for children with ASD. Therefore, findings to date suggest both developmental delays in emotion regulation strategies in preschoolers with ASD, particularly for strategies facilitating the shift from co-regulation to self-regulation during early childhood (e.g., Cole et al. 1994), and a qualitative difference in the types of strategies that work for preschoolers with ASD compared to typically developing preschoolers.

Children learn how to process and manage their emotions via parental modelling and guidance (Eisenberg et al. 1998). Indeed, recent findings suggest that parent-facilitated emotion regulation, specifically strategies that encouraged children to self-regulate their emotions, in preschoolers with ASD predicts positive self-development and school engagement 2 years

later (Nelson et al. [under review](#)). Consistently, Gulsrud et al. (2010) found that higher use of maternal strategies with toddlers with ASD that aimed to manage the child's stress *for them* (prompting, physical comfort, and redirection) was related to more frequent externalizing behaviors. This could suggest the need to put a stronger emphasis on supporting *self*-regulation in ASD versus externally supported regulation. Higher use of maternal vocal strategies (vocal comfort and reassurance), on the other hand, was related to less child stress (Gulsrud et al. 2010). However, in older children with ASD, higher parental scaffolding has been found to predict less child dysregulation in a dyadic context (Fenning et al. 2018) and less externalizing (but not internalizing) problems during anger/anxiety episodes, after controlling for child age and IQ (Ting and Weiss 2017). Children's own use of certain types of strategies also may impact those around them; Nuske et al. (2018) found that preschoolers with ASD that used two passive emotion regulation strategies (self-soothing, deep exhalation) more frequently were in families that reported a lower family quality of life.

The findings reported above highlight, in particular, the importance of supporting self-regulation and independence in children with ASD. Based on the research in this area, appropriate intervention strategies to support self-development in children with ASD, via targeting self-other mapping and self-awareness, may include imitation of the child, use of child names to refer to their body movements (e.g., walking), states (e.g., tired), permanent relations of possession (e.g., clothing), and photographs of themselves, modelling of personal pronouns during self-propelled actions on objects, turn-taking, and visuospatial perspective-taking games and the creation of stories where the child is the main protagonist (Charney 1980; DeSocio 2005; Hobson 1990, 2010; Loveland 1984; McLean et al. 2007). Given that agency and internal motivation are recognized as integral to self-development (Deci and Ryan 1980; Ryan and Deci 2000), interventions that offer children choices and capitalize on their interests as teaching props and reinforcers (e.g., naturalistic

developmental behavioral interventions; Schreibman et al. 2015) will also incidentally support self-development.

Future Directions

Although there has been a marked increase in emotion regulation research in ASD, there are still several gaps and important areas for future research. First, as argued here, the preschool period is critical for emotion regulation development and requires more attention. The majority of research thus far has focused on characterizing strategy use, and treatment development efforts could be supported by the identification of mechanisms or processes that may contribute to delayed or atypical emotion regulation development.

Many studies in the area did not report information on the actual experienced emotion of the children (e.g., coding of child emotional reactivity, physiological markers of stress). An important next step for future research is to examine how emotion regulation strategy use impacts, and is impacted by, the experienced emotion in children with ASD. Particularly in the preschool age range, it will be essential to also consider how the expressed emotion may impact the bidirectional relationship between the parent or other significant adults in the child's life and the child, as it related to emotion regulation development. Beyond emotion expression, it may further be helpful to consider how other aspects of emotional development, such as emotion recognition and emotion awareness, impact emotion self-regulation.

As this field moves forward, it would also benefit from enhanced methodological rigor, especially the use of multimethod assessment approaches, preferably incorporating measures validated in ASD, and longitudinal studies. Longitudinal research may help inform which aspects of emotion regulation increase risk for later problems. Importantly, there is great variability in emotion regulation development in ASD, and it will be important to understand factors that are associated with more positive trajectories. Along these same lines, the emotion regulation

research has emphasized the regulation of negative emotion, but it is equally important to understand how preschoolers with ASD learn to regulate positive emotion. Since neuroimaging work suggests emotion regulation is central to self-development (Pfeifer and Peake 2012), future research is also needed to delineate the developmental bidirectional relationship between emotion regulation and broader self-development.

Finally, further research on the strategies to support emotional self-regulation in ASD is needed. There are some small studies suggesting that emotion regulation can be improved with intervention in older preschool-aged children ASD (e.g., Scarpa and Reyes 2011), but emotion regulation has generally not been measured of an endpoint in any clinical trials with younger preschool children. Even among older children, adolescents, and adults, the treatment literature on emotion regulation is markedly limited, with only recent developments in this area (e.g., Conner et al. 2019). Given the accumulating evidence linking poor emotion regulation to negative outcomes, greater focus on treatment development and testing to improve emotion regulation is a priority. It will be important to consider the best means to deliver such interventions during the preschool period, such as embedded within broader treatment programs, in school settings, or with parent-supported delivery to support generalization of effects.

Emotional Intelligence

Liz Pellicano

Centre for Research in Autism and Education (CRAE), Department of Psychology and Human Development, Institute of Education, University of London, London, UK

Definition

Emotional intelligence is defined as “the capacity to reason about emotions, and of emotions to enhance thinking. It includes the ability to accurately perceive emotions, to access and generate emotions so as to assist thought, to understand emotions and emotional knowledge, and to reflectively regulate emotions so as to promote

emotional and intellectual growth” (Mayer et al. 2004, p. 197).

Historical Background

Mayer and colleagues (Mayer et al. 2004; Mayer and Salovey 1993) view emotional intelligence as belonging to what they term “hot intelligences,” which essentially operate at the intersection of emotion processing and higher-level cognition, that is, between thinking and feeling. This conceptualization is reflected in their “four-branch ability model” in which they propose the following components of emotional intelligence: (1) perceiving emotion, (2) using emotion to assist thought, (3) understanding emotions, and (4) managing emotions in oneself and in others.

Current Knowledge

The concept of emotional intelligence (or “EQ”) has captured the imagination of non-psychologists, who have broadened the term to include not only the ability to understand and use emotional information but also to describe personality attributes and the capacity to relate to others in social situations (e.g., Goleman 1998). The concept is not without controversy, however. Academic scholars have been less willing to adopt the term “emotional intelligence” in scientific parlance, and the construct as described above has not been the subject of sustained, systematic investigation. Indeed, it has been described as an “elusive concept” (Davies et al. 1998, p. 989), one which “appears more myth than science...” (Matthews et al. 2002, p. 547).

Emotional Intelligence in Autism

Perhaps unsurprisingly, the term “emotional intelligence” has not been embraced by researchers in the field of autism. In fact, a PubMed search for articles from January 1970 until August 2011 with the terms “emotional intelligence” AND “autistic disorder” OR “autism” yielded 17 articles of which only one directly investigated emotional intelligence in autism (Petrides et al. 2011).

These authors reported lower scores on a trait emotional intelligence measure by adults with Asperger syndrome relative to typical adults.

This is not to say that the majority of the “processes” in Mayer et al.’s “branches” have not been systematically studied in autism, albeit under different – and arguably better validated – guises.

First, there is an extensive body of work investigating how people with autism perceive and recognize emotion in faces, voices, and other non-verbal cues (Branch 1). Second, the critical role that emotion plays in decision making and executive functions more broadly has been well documented in the burgeoning social neuroscience literature (e.g., Damasio 1994; Pessoa 2008). There have been several recent investigations of social decision making – problems that involve the regulation of affect and motivation – in autism (using the Iowa gambling task, for example), although there have been comparatively fewer investigations of the development of these processes either under the headings of “self-regulation” (Posner and Rothbart 2000) or “hot executive function” (Carlson et al. 2005; Happaney et al. 2004) (Branches 2 and 4). Finally, Baron-Cohen’s (2002) “empathizing” construct covers many of the abilities described in Branch 3 – those that are important for both identifying the thoughts and feelings of others *and* using that information to respond in appropriate ways – which may overlap with other heavily researched constructs like “theory of mind.” Indeed, Blair (2002) considers whether theory of mind might be a necessary prerequisite for the development of emotional intelligence.

Future Directions

Despite the limited empirical focus on the nature of the construct of emotional intelligence in autism, references to autistic individuals’ “lack of emotional intelligence” abound in the popular press and on the Internet. Caution is warranted, however, on the use of these and other extreme statements (e.g., “zero degrees of empathy”; Baron-Cohen (2011), etc.) (see Pellicano and

Stears 2011): They are often considered disparaging to the individuals concerned and often accurately reflect neither the empirical data nor the inner emotional lives of many people with autism (Cohen-Rottenberg 2011). Future research will need to take a more nuanced approach.

Emotional Processing in ASD

Elizabeth J. Teh

Department of Otolaryngology, Yong Loo Lin School of Medicine, National University of Singapore, Singapore, Singapore

Definition

Emotional processing refers to the ability to evaluate one's own and others' feelings, using information from current cues and prior knowledge about social relationships and contexts. Relevant emotional information includes visual cues, such as facial expressions, body posture, and gestures, and auditory cues such as vocal expressions (e.g., sighs and exclamations), prosody, and tone of voice. Emotional information may also be present in written text and spoken conversation. Being able to process emotional information is a developmental skill that increases in competence and complexity as children learn to identify people's feelings in social situations, attribute reasons for the emotions, and regulate their own behaviors and emotional responses to achieve social goals (Lerner and Arsenio 2000).

Emotional processing can be indexed by an individual's ability to recognize and label

emotions, describe emotions, and reason about possible causes of emotions. These tasks involve skills in information-processing and social cognition, including deriving emotional meaning from single or multiple cues, applying learned information about emotional responses and social norms to current situations, taking others' perspectives, and inferring others' internal states and intentions. The ability to make use of relevant background knowledge is particularly important for evaluating emotions that are socially based in interpersonal relationships or situations (e.g., *jealousy*, *pride*, *shame*), whereas basic or nonsocial emotions can sometimes be inferred from surface cues without reference to other people or the environment (e.g., *happiness*, *fear*). Social cognitive and emotional processes appear to be highly interconnected in neurotypical individuals (Olsson and Ochsner 2008), but these processes may not be as well integrated in individuals with ASD (Happé and Frith 2014).

In general, emotional processing in individuals with ASD tends to be impaired when compared to neurotypicals, including deficits in recognizing others' emotions, using emotional language, describing emotional concepts, and attributing causes for emotions. Further, processing of social emotions tends to be more impaired than of nonsocial emotions (Williams and Happé 2010). However, variability in abilities exists, and performance seems to be associated with cognitive, linguistic, and theory of mind abilities. The development of language-based empirical methods to investigate emotional processing in ASD has also facilitated an emerging view that emotions may be conceptualized, and/or experienced, differently in individuals with ASD (Losh and Capps 2006).

Historical Background

Kanner's (1943) seminal paper entitled *Autistic Disturbances of Affective Contact* documented multiple features suggesting innate emotional abnormalities in autistic children, including a "profound aloneness" (p. 248). He noted the extreme lack of interest in interpersonal relations which contrasted starkly with their ability to

maintain a meaningful relation to objects. Supporting Kanner's position, early experiments on emotional recognition reported that children with autism spectrum disorders (ASD) were less able to discriminate and recognize people's emotions from facial expressions, vocal expressions, and gestures, than non-autistic children matched on age, cognitive functioning, and/or language development (e.g., Hobson 1986a, b). Such findings contributed toward a prevailing view that there existed a "basic" social-affective impairment in children with ASD which reduced their performance in emotion recognition tasks above and beyond any deficits in domain-general cognitive processing and/or language abilities (Fein et al. 1986; Hermelin and O'Connor 1985). However, results from subsequent research were more equivocal and included reports of near-normative performance in recognizing at least one emotion, *happiness*, by individuals with ASD (see review by Uljarevic and Hamilton 2013). This variability in findings may be partially attributable to differences in sample characteristics such as chronological age, cognitive, and language abilities (Begeer et al. 2008; Lartseva et al. 2014). Crucially, methods using expressive language paradigms have allowed researchers to observe difficulties or differences in the conceptualization of emotions in individuals with ASD, compared to typically developing controls. Hence, instead of a universal emotional processing deficit in ASD, recent reviews point to the individual nature of the pattern of impairments (Leekam 2016; Nuske et al. 2013). The next section will provide a summary of the current knowledge arising from the variety of empirical methods that have been developed to characterize the patterns of skills and deficits in emotional processing in individuals with ASD.

Current Knowledge

Emotional processing has been studied both in terms of emotional recognition and emotional expression in individuals with ASD. Emotional recognition paradigms facilitate an examination of how individuals with ASD perceive and

evaluate different types of emotional cues. By comparison, emotional expression paradigms allow researchers to study the extent to which individuals with ASD conceptualize and reason about emotions in themselves and others. Findings from the different paradigms will be discussed in turn below, followed by a brief consideration of theoretical models of ASD that may explain the emotional processing deficits.

Emotional Recognition

Recognition from visual and auditory stimuli.

Early studies sought to examine ability to discriminate and recognize emotions in other people. The classic emotional processing experiment is where participants are presented with stimuli and asked to match or label the emotions depicted. Emotional stimuli include face photographs (e.g., Tantam et al. 1989), video clips where a person portrays different emotions in isolation or in contextualized scenarios (e.g., Hobson 1986a), video clips showing bodily expressions of emotions with the actor's face obscured (Hobson 1986b), and audio clips of emotionally expressive voices (e.g., Hobson et al. 1988). In these studies, emotional processing involves evaluating facial expressions, prosodic cues, "body language," and/or contextual cues. Multiple early studies reported that children with ASD were less accurate at recognizing emotions from faces and voices than comparison groups matched on one or more variables of chronological age, cognitive functioning, and verbal abilities (e.g., Hobson 1986a, b; Hobson et al. 1988).

However, later studies did not always find significant group differences in abilities (e.g., Prior et al. 1990). Uljarevic and Hamilton's (2013) meta-analysis of 48 emotion recognition studies using picture matching/labeling experiments revealed that there was a large overall emotion recognition deficit (Cohen's $d = 0.80$) in children and adults with ASD compared to control groups matched on age, IQ, and/or verbal ability. The emotions tested were one or more of the six basic or nonsocial emotions: *happiness*, *sadness*, *anger*, *fear*, *disgust*, and *surprise* (see Emotion). Basic emotions are typically recognized relatively early in development (Izard 1977), can often be

identified from surface cues such as smiles (for *happiness*) and frowns (for *anger*), and are non-social in the sense that they can be felt without reference to other people (Heerey et al. 2003). Despite reporting an overall mean emotion recognition deficit in ASD, Uljarevic and Hamilton noted the large variability in outcomes across studies and the lack of a significant correlation with age or IQ. Additionally, participants with ASD showed near-normal recognition of one emotion, *happiness*, which suggests that processing is not equally impaired for all types of emotions. Interestingly, studies comparing recognition of negative and positive emotions reported that adults with ASD made more errors on negative emotions, particularly *fear*, than on positive emotions, whereas no such valence effect was seen in typically developing adults (e.g., Ashwin et al. 2006; Philip et al. 2010). This suggested that valence may moderate emotional recognition abilities in ASD.

Recognition in text. Besides facial stimuli, researchers have investigated the ability of individuals with ASD to recognize emotions in spoken and/or written text, at the level of words (e.g., Järvinen-Pasley et al. 2008), sentences (e.g., Grossman et al. 2010), and stories (e.g., Hillier and Allinson 2002). Participants are usually asked to identify emotions explicitly stated in the stimuli (e.g., *happy* emotion: "I am feeling happy today"), to infer emotions from the text (e.g., *sad* emotion: "John cried when he lost his dog"), or, in the case of spoken stimuli, to infer emotions from its prosodic intonation. There are mixed findings from these text paradigms. Some researchers have found poorer accuracy of emotional judgment in participants with ASD than in typically developing controls matched on age, IQ, and/or verbal ability (e.g., Järvinen-Pasley et al. 2008), while others have reported no group differences in abilities (e.g., Grossman et al. 2010).

Compensatory strategies for emotional recognition. One caveat arising from findings with visual, auditory, and text stimuli is that individuals with ASD who have higher cognitive functioning and/or language abilities may be able to use alternative strategies to decode emotions. For example, they could analyze or draw upon

lexical knowledge for emotional words. A review by Begeer et al. (2008) reported that children with ASD with average or above-average IQ can recognize basic emotions in pictures on a par with age-matched typically developing children, whereas children with ASD with a lower IQ may have difficulty even with basic emotions. Lindner and Rosén (2006) compared ability to recognize emotions from video and audio stimuli, with and without verbal content, and found that verbal content facilitated emotional understanding in children with ASD (Asperger Syndrome), i.e., linguistic information might have been used as a compensatory strategy for deficits in emotional processing of facial expressions and prosody.

Hence researchers have argued that laboratory tasks on emotional recognition in individuals with ASD requiring explicit emotional judgments do not necessarily measure emotional processing abilities alone. Moreover, other studies using implicit emotional processing paradigms have shown that emotionality significantly affects response time and/or accuracy in typically developing controls (e.g., in memory or word repetition tasks), but it has limited or no influence on performance in individuals with ASD (Deruelle et al. 2008; Singh and Harrow 2014). Taken together, the results suggest a selective impairment in spontaneous processing and integration of emotional cues in individuals with ASD, which may reduce their ability to evaluate and learn about emotions in real-life experiences. To better measure spontaneous emotional processing and gain insight into the conceptual understanding of emotions in individuals with ASD, emotional expression paradigms may be used.

Emotional Expression

Emotional language use. The quantity and appropriateness of emotional labels produced in language samples is one way to compare spontaneous emotional processing in individuals with and without ASD. Researchers have collected language samples by eliciting story narratives using sequenced pictures (e.g., Canfield et al. 2016), picture books (e.g., Rumpf et al. 2012), or contextualized social and/or emotional pictures

(e.g., Teh et al. 2018). Other researchers have recorded language samples from participants during conversations with their family members (e.g., Tager-Flusberg 1992) or with the experimenter on selected emotional and nonemotional topics (e.g., Bang et al. 2013). Some researchers have reported fewer emotional terms produced by children with ASD compared to matched typically developing children (Canfield et al. 2016; Teh et al. 2018) or to age and IQ/verbal IQ-matched controls in other clinical groups (e.g., Tager-Flusberg (1992) on children with ASD and children with Down's syndrome). In contrast, others have reported no significant differences in production of emotional terms between groups with and without ASD (Bang et al. 2013; Rumpf et al. 2012). Two studies have reported a greater use of negative than positive emotional language by both children with ASD and typically developing children (Rumpf et al. 2012; Teh et al. 2018), but little is currently known about valence effects in this area. However, the quantity of internal state language (including emotions) is associated with age and theory of mind skills (Siller et al. 2014) and cognitive ability (Capps et al. 2000), so variability in sample characteristics could partially explain the mixed findings in the literature. It should also be highlighted that most studies included emotional language production as part of investigations into broader discourse skills, such as narrative organization and conversational skills, which are often impaired in children with ASD (Canfield et al. 2016; Bang et al. 2013). Thus, further studies designed to look specifically at emotional processing abilities are needed, with well-characterized samples, before these findings can be integrated productively.

Reasoning about emotions. Contrasting with the mixed picture on use of emotional language above, children with ASD have been consistently reported to show challenges with reasoning about emotions. In story narratives, children with ASD reportedly make fewer causal attributions for emotions than matched typically developing children, and the causes they suggest tend to refer to characters' actions or visually salient emotion cues, rather than the characters' intentions or desires (Canfield et al. 2016; Capps

et al. 2000). These findings are consistent with reported theory of mind deficits in ASD that reduce their ability to appreciate or evaluate others' mental states (Baron-Cohen et al. 1985; see ► [Theory of Mind](#)). Additionally, when talking about their own emotional experiences, children with ASD tend to attribute their emotions to events and actions, whereas typically developing children commonly contextualize their emotions within a personal or social perspective (e.g., Losh and Capps 2006; Rieffe et al. 2007). Such group differences in reasoning about emotions raises the question of whether conceptualization of emotions may differ in children with ASD and typically developing children.

Emotional concepts. Data from emotion interviews reveal that emotional concepts may be underdeveloped in children with ASD. In emotion interviews, participants are asked to define named emotions, describe situations that exemplify those emotions, and/or share personal experiences of the named emotions. Researchers have commented that descriptions and personal accounts of emotions by children with ASD tend to be less coherent and less detailed than those of typically developing controls (e.g., Ben-Itzhak et al. 2016; Rieffe et al. 2007). The result is descriptions that sometimes appear inappropriate, although not completely wrong, for the named emotions (e.g., feeling *proud* upon receiving a present; Losh and Capps 2006). Moreover, Yirmiya et al. (1992) reported that performance correlated positively with cognitive functioning in ASD, a relationship which was not present in typically developing control children, again suggesting that emotional processing in ASD may be mediated by other developmental skills. Additionally, ability to process negative emotions may be more impaired than positive emotions in children with ASD, as evidenced by fewer reports and poorer descriptions of negative than positive emotions by children with ASD compared to typically developing children (e.g., Ben-Itzhak et al. 2016; Rieffe et al. 2007). Furthermore, impairments with emotional concepts may be influenced by challenges in relating social contexts and relationships to emotional outcomes, as discussed next.

Moderating effect of social context.

Emotional processing is often closely related to processing of social information. However, for people with ASD, social cognitive studies have generally revealed deficits in the ability to perceive and/or interpret social cues, link socially relevant stimuli with retrieval of social knowledge, and evaluate others' social intentions (e.g., Flood et al. 2011). Teh et al. (2018) demonstrated that increasing social engagement information in pictures reduced the frequency of emotional language produced by children with ASD, but increased production of emotional language by typically developing children, particularly in positively valenced conditions. Perhaps social contexts require complex processing skills due to multiple sources of information, including current cues and prior knowledge, that need to be integrated to support emotional processing (Minshew and Goldstein 1998). Presumably, the need to process and integrate multiple cues explains why socially based emotions, such as *embarrassment*, *pride*, or *shame*, are reportedly more challenging for children with ASD to recognize (Williams and Happé 2010) and describe (Heerey et al. 2003; Losh and Capps 2006) than nonsocial emotions, since socially based emotions require an ability to consider others' perspectives and have an awareness of social norms and their violations. The processing imbalance between social and nonsocial emotions has also been observed in children with learning disabilities (Williams and Happé 2010). Hence, recent reviewers have debated whether and how emotional processing in ASD may be associated with broader deficits in ► [“Social Cognition”](#) characteristic of ASD and/or other domain-general information-processing deficits (Leekam 2016).

Theories Underlying Emotional Processing Deficits in ASD

There are at least four theories explaining emotional processing deficits in ASD: (1) reduced social motivation in ASD (see review by Chevallier et al. 2012), which partially explains lack of attention to social stimuli; (2) cognitive attention biases and rigidity or selective complex processing impairments (Minshew and Goldstein 1998) that

reduce the ability of people with ASD to combine and interpret multiple contextual cues and use relevant background knowledge to understand emotions; (3) theory of mind impairments that limit ability to attribute mental states to others (Baron-Cohen et al. 1985); and (4) ► “Weak Central Coherence”, which helps to explain difficulties in holistically processing relevant cues from the face, voice, body posture, and/or situational contexts to understand emotions (Happé and Frith 2006). However, no one theory is yet able to adequately explain the range of emotional processing skills and deficits reported in ASD. Furthermore, age, language, and cognitive skills may be positively associated with theory of mind development, social motivation, or even global processing abilities (Begeer et al. 2008; Steele et al. 2003), but the uneven profile of these skills in ASD has made these relationships difficult to ascertain.

Summary

Taken together, the extant research on recognition and expression of emotions by individuals with ASD has revealed quantitative and qualitative variation in the pattern and extent of emotional processing skills and impairments in ASD, across a wide range of experimental paradigms. While there is a general consensus in the literature that emotional processing is impaired in ASD compared to typically developing controls, there are contrary findings in studies that may be partially attributable to participant sampling. More recent evidence from self-report studies suggest that emotional concepts are underdeveloped in children with ASD (Rieffe et al. 2007). There is also emerging evidence that the pattern of emotional processing deficits may be uneven across conditions of valence and social engagement. Given that the range of skills and deficits is so varied, more than one mechanism appears to underlie emotional processing deficits in ASD. Further research is needed to clarify all these points.

Future Directions

After decades of research on emotional processing skills in ASD, the question remains unanswered

about whether emotional processing deficits are core in ASD symptomatology, as originally proposed by Kanner (1943), or whether deficits arise as a downstream effect of social cognitive deficits or other domain-general processing difficulties. Longitudinal studies may be useful to observe development of skills with age in children with ASD and may eventually enable researchers to unravel cause-and-effect relationships among social/emotional learning and domain-general cognitive, linguistic, and other skills development. Alternatively, more cohort studies are needed, using well-characterized samples on variables such as age, cognitive functioning, language, and theory of mind development, because the heterogeneous nature of ASD has made it difficult so far to integrate findings across studies and systematically explore relationships between participant characteristics and emotional processing.

Questions also remain over how processing of basic (nonsocial) and complex (social) emotions is different in individuals with ASD compared to other groups. A few studies have demonstrated valence effects on emotional recognition and expression in ASD, but research remains sparse in this area, and little is known about the processing of emotionally neutral situations in ASD (Uljarevic and Hamilton 2013). Hence, it is important for future researchers to systematically manipulate valence and social variables in experimental stimuli in order to examine their separate or combined/interactive effects on emotional processing. Lastly, emotional language use by individuals with ASD is an area that has received limited attention in the literature to date (Lartseva et al. 2014). Studies using this measure have revealed quantitative and qualitative differences in the way people with ASD process and respond to emotional stimuli compared to typically developing controls. Emerging findings from children with ASD also suggest that differences exist in the way emotions are conceptualized from young, in terms of how they reason about and/or experience emotions. Thus emotional language research shows potential to shed light on many questions regarding emotional processing skills in ASD, and further work in this area will be useful.

Emotional Regulation

Walter Gilliam

Child Study Center, Yale University School of Medicine, New Haven, CT, USA

Synonyms

[Affective regulation](#); [ER](#)

Definition

Emotional regulation (ER, also known as affective regulation) is an area of research that has experienced significant growth in interest during the last two decades. In brief, ER is a person's attempt to regulate or influence the type and degree of emotional response he or she has to a stimulus, the timing of that emotional response, how that emotional response is experienced, or how that emotional response is expressed to others (Gross 2007). ER capacity is a person's ability to regulate their emotions toward adaptive ends.

ER is an aspect of self-regulation. All living organisms engage in processes of self-regulation in order to adapt to environmental demands. In humans, self-regulation is a developmental process, by which individuals gain greater control over their own physiological, emotional, cognitive/attentional, and behavioral responses to their environments. These response domains and their regulation are interrelated. When the environment poses manageable challenges to which a person

can draw upon his or her personal resources to meet these challenges, self-regulatory capacities are strengthened and adaptive development occurs. When the environment poses challenges beyond the capacities of the individual to adapt, maladaptive or disordered patterns of behavior may become evident (National Research Council & Institute of Medicine 2000).

Emotions play an important role in social relationships, both as a way to respond to others and as a way to elicit social connections from others. During typical development, emotional expression develops from generalized arousal states (e.g., a “fussy” baby) to more differentiated emotional responses (e.g., anger, sadness, frustration, fear), while the development of cognitive capacities helps the person to better understand the environmental antecedents of their emotional responses, identify emotional states in others, and develop self-coping strategies. These self-coping strategies are often mediated by language (self-talk), and evidence has long suggested that delayed or impaired language development may have a negative impact on the development of ER.

Aspects of ER capacity include the ability to identify one’s own feelings, to identify feelings in others and empathize, and to manage one’s own feelings toward constructive or adaptive ends. As in other areas of self-regulation, the development of ER capacities evolves from mostly external regulation (e.g., reliance on caregivers to soothe and modulate emotional response) to increasingly internal regulation (e.g., self-soothing and self-modulation of emotional expression). In most young children, external regulation of emotion can be easily seen during frequent social referencing – the tendency to look at a trusted caregiver for cues as to the appropriate emotional response. Temperament (an individual’s typical responses to environmental demands and novel stimuli and ability to regulate emotional and arousal responses to these stimuli) is a related construct.

Self-inhibitory skill (also described as effortful control) is central to the development of ER. This is the ability to behaviorally inhibit a natural emotional response in order to obtain a more socially

desirable outcome (e.g., not hitting someone when angry). Individuals who are poor at effortful control often experience difficulty with social relationships with peers, caregivers, and authority. ER, however, is not about the suppression of emotion, but rather about understanding emotions within social contexts and how to modulate emotional expression in adaptive ways. A greater capacity for ER helps one to be able to better regulate strong emotions, deal with fearful and frustrating events, and form and maintain meaningful and beneficial social relationships.

ER capacity is influenced by a person’s temperament, diagnosable disorders that may impact a person’s ability to attend to socially salient information, the degree of demands placed upon the individual by his or her environment, and executive functioning skills (e.g., attending to important environmental details, forming a symbolic understanding of the environment and how aspects of the environment interrelate, planning behavioral responses, sustaining and shifting attention, inhibiting, and self-reflecting). Cultural values also exert a strong influence by influencing caregiver responses to emotions and preferred methods for dealing with strong emotion.

Efforts to facilitate ER capacities have included teaching children to identify and label emotional states in themselves and others, to choose between a variety of potential emotional and behavioral responses, to delay gratification, and to use self-relaxation techniques.

Emotion-Focused Therapy for Autism Spectrum

Anna Robinson
Centre for Autism Studies, Scottish Centre for
Applied Autism Research, University of
Strathclyde, Glasgow, UK

Definition

Emotion-Focused Therapy for Autism Spectrum (EFT-AS) is a small group version of Emotion-Focused Therapy (EFT) that provides a client-led framework within a process-guiding, task-oriented structure (Robinson and Elliott 2017). EFT-AS is a humanistic-experiential psychotherapy (HEP), which focuses on accessing and transforming core painful feelings often as a result of continued relational injuries through interpersonal encounters. EFT-AS uses the therapist relational stance, evocative process-guiding tasks, group member exchanges, and video Interpersonal Process Recall (IPR) to address core aspects of

emotion regulation, including cognitive-affective empathy to enhance intra- and interpersonal understanding.

Historical Background

Emotion-Focused Therapy (EFT) (Elliott et al. 2004; Greenberg et al. 1993) was developed as a treatment using broadly universally applicable principles to various client presentations. EFT has been used as a treatment for major depression (Greenberg and Watson 1998, 2006; Goldman et al. 2006), with clients suffering from abuse (Paivio and Greenberg 1995), trauma (Elliott et al. 1998), complex trauma (Paivio and Pascual-Leone 2010), and eating difficulties (Dolhanty and Greenberg 2007), and more recently as a treatment for social anxiety (Elliott 2013; Shahar 2014) and generalized anxiety (Timulak 2015). EFT has been further adapted to meet the specific emotional processing differences of clients on the autism spectrum (Robinson and Elliott 2017).

Rationale or Underlying Theory

Emotion-Focused Therapy (EFT) is an evidence-based humanistic-experiential psychotherapy (HEP). EFT combines relational principles from the person-centered approach (Rogers 1951) with more directive evocative interventions from Gestalt and other experiential therapies (Greenberg et al. 1993). As a humanistic therapy, it is grounded in values of authenticity, growth, self-determination, creativity, and pluralism, with the therapeutic relationship seen as a key curative element. It integrates active approaches of psychodrama (Moreno and Moreno 1959) and process-guiding methods from Gestalt therapy (Perls et al. 1951; Perls 1969) and experiential therapy, specifically Gendlin's Focusing (1981). Emotion-Focused Therapy for Autism Spectrum (EFT-AS) is an integrative group psychotherapy approach grounded in humanistic values and EFT theory and practice and uses video Interpersonal Process Recall (IPR; Kagan 1984) as a process-guiding method making experiential and self-

other relational processing more accessible and concrete.

EFT aims at helping clients to better deal with their emotions; to attend to, accept, symbolize, and make sense of them, for emotion regulation; and, ultimately, to restructure maladaptive emotion schemes that underlie client symptoms (Greenberg et al. 1993; Greenberg and Watson 2006). EFT uses several sets of concepts in its theory of function and dysfunction, including emotion schemes, emotion response types, and emotion regulation. According to EFT, emotions have an innately adaptive potential, which, if activated, can help clients change problematic emotional states or unwanted self-experiences. Therapeutic change in EFT is perceived as resulting from restructuring the cognitive-affective schemes that underlie presenting symptoms.

EFT involves changing emotion with emotion by accessing and transforming maladaptive emotions schemes (e.g., shame, fear, and lonely abandonment) underlying presenting symptoms. As clients on the autism spectrum often have difficulty accessing their emotions (Mazefsky et al. 2013) and episodic memory recall (McDonnell et al. 2017), EFT-AS uses video Interpersonal Process Recall as a clinical process-guiding method to facilitate client awareness and arousal. Specifically, to scaffold areas of difficulty related to affective empathy for self (emotional self-attunement or processing own emotions) and for other (interpersonal attunement or empathic relating) and also areas of difficulty related to cognitive empathy for self (self-understanding, reflection, and conception or theory of own mind (Williams 2010)) and for other or theory of your mind/mental representation (Baron-Cohen 1997). People on the autism spectrum are vulnerable to trauma-related experiences due to a diminished sense of self and lack of self-agency within interpersonal engagement (Robinson 2018). In EFT-AS, a main therapeutic task is repairing emotional hurt resulting from continued relational injuries through interpersonal conflict encounters. Clients on the autism spectrum work in a group setting to evoke and transform painful emotions, both directly and vicariously.

Goals and Objectives

Several goals have been addressed using Emotion-Focused Therapy for Autism Spectrum (EFT-AS). The main focus of EFT is to help clients to access maladaptive emotions and to transform these to useful adaptive emotions. Individuals on the autism spectrum can have difficulties in emotion processing, including recognizing their own and others' emotions, leading to problems in emotion regulation and interpersonal relating. The main focus in EFT-AS is working with emotional injuries to better aid emotion regulation, including cognitive-affective empathy to enhance intra- and interpersonal understanding. The therapeutic tasks evoke internal bodily focus on emotions, accessing not fully processed trauma-related experiences and compassion responses to self and to other while encoding and symbolizing new adaptive emotions.

The published research to date presents clinical case conceptualizations of clients working through different aspects of intra- and interpersonal distress. EFT-AS is marker driven and uses intra- and interpersonal markers as indicators of client readiness for engagement in therapeutic tasks. As a group therapy, it offers dynamic opportunities for clients to work on their own presenting issues, interpersonal opportunities between group members and opportunities for attachment patterns to be played out within the microcosm of the group.

One of the key presenting triggers bringing clients on the autism spectrum to therapy is interpersonal/relational issues, and these have been successfully worked with using a misempathy task (Robinson and Elliott 2017). A second presenting trigger bringing clients to therapy is social withdrawal, isolation, and loneliness. The group dynamic can reduce immediate feelings of social isolation, and it has been successfully used with clients working through emotional injuries from trauma-related experiences (Robinson 2018). A third presenting trigger bringing clients on the autism spectrum to seek therapy is feelings of extreme alienation and a sense of otherness, and this has been worked with successfully through a model of interpersonal rupture and repair (Robinson 2019).

Treatment Participants

EFT-AS is aimed at providing therapeutic support to adolescents and adults on the autism spectrum with no additional intellectual disability and complex communication needs: specifically, for people who are seeking psychological support due to emotional distress and who are struggling to understand themselves and their current and previous life experiences; for those who find others, particularly their typical development (TD) peers, difficult to understand; further, for those who are isolated and withdrawn who may have a co-occurring depression or anxiety disorder (social anxiety, generalized anxiety); and those who have experienced previous trauma-related difficulties through chronic peer victimization and bullying, social rejection, and loneliness through lack of social opportunity and friendship.

Treatment Procedures

Emotion-Focused Therapy for clients on the Autism Spectrum offers a humanistic client-led interpersonal framework within an experiential process-guiding, task-oriented structure. EFT-AS follows a 3-step model consisting of two kinds of alternating sessions: a group therapy session and a video-assisted Interpersonal Process Recall (IPR) session. It is a brief group treatment lasting a minimum of 9 weeks but can be extended in two-weekly cycles of therapy and IPR-assisted sessions, with an ending session in the final week. It is a small group format with between three and six clients and co-facilitation with two therapists. All sessions are video recorded, and the therapist analyses each therapy session (session 1, 3, 5, 7, and so on) to identify therapeutic task markers. The therapist edits three short clips that contain the task marker, which may be multiple markers for multiple members. The therapist plays these edited clips in the following IPR sessions (session 2, 4, 6, 8, and so on).

The therapist offers empathic attunement with client emotions, helping clients by focusing

attention on bodily feelings and by offering experiments in directed awareness and emotion stimulation using imagery and psycho-dramatic enactments, interpersonal exchanges, and video-IPR. Each session offers a familiar sequence, beginning with a transition task signaling the beginning of the therapy session. This is followed by a check-in which offers an opportunity to work toward what the client wants to accomplish and space to identify unfinished business from the previous session. Next, the therapist facilitates a guided focusing task aimed at helping clients focus attention to their inner bodily feelings.

As EFT is marker driven, the therapist looks for a task marker (emotion marker which is a behavior or discourse that indicates a client's readiness to engage in therapeutic work). In EFT-AS, the therapist uses these task markers in two ways. The first is in the moment to guide self- and other experiential processing tasks, and the second is through IPR clip selection to set up tasks in the following IPR session. Once the marker is identified, the therapist is guided by the emotion transformation model which provides a clinical strategy for emotional deepening that consists of several aspects within three phases. First, the therapist approaches emotions and explores client distress. At the beginning, the therapist works mostly with client global distress, that is, undifferentiated distress, to identify triggers (historical and current), negative self-treatment (negative self-talk), and avoidance behaviors (actions, thinking, and emotion). The therapist uses different emotion stimulation tasks to explore global distress and secondary emotions such as reactive anger, shame, or fear.

In the second phase, the therapist assists the client in moving toward painful and avoided emotions that have not been fully processed, staying with and deepening painful experience to reach core maladapted emotions. Once the client reaches the core emotion, the stuck painful feelings that hurt the most, the therapist helps the client to articulate the unmet need associated with that core pain.

In the third phase, the therapist uses emotion stimulation using imagery and psycho-dramatic

enactments to evoke new primary adaptive emotions and more adaptive experiences of self and others, such as self-compassion, self-soothing, and assertive anger. These are useful feelings that fit the immediate situation and provide a direction forward. The main tasks entail the use of imaginary chair dialogues such as two-chair dialogue for conflict split, two-chair dialogue for self-interruption, or empty chair dialogue for unfinished business (Elliott et al. 2004). EFT-AS uses a range of adapted therapeutic tasks to make this more accessible to the processing differences of those on the autism spectrum. The addition of video IPR can be used to scaffold retrieval of autobiographical memory recall for distanced trauma-related experiences evoking and activation of emotions associated with the event and experiential processing of these emotions. It can act as a visual concrete part of self (e.g., fragile self) for empty-chair work, to speak their truth to a significant other (e.g., a lost parent) or express their anger to a harmful other (e.g., abusive bully). Further, it can be used to evoke emotional responses to self, such as self-compassion and also to evoke interpersonal emotional responses, such as expressing and receiving compassion to and from group members. The emerging adaptive emotions facilitate mentalization of self (theory of own mind) and other (theory of your mind) that strengthens intrapersonal and interpersonal agency.

Efficacy Information

Emotion-Focused Therapy (EFT) is an empirically supported humanistic-experiential psychotherapy (HEP). Emotion-Focused Therapy in its individual form has been reported to be successfully applied for the treatment of depression (Greenberg and Watson 2006), adult survivors of childhood sexual abuse and complex trauma (Paivio and Pascual-Leone 2010), social anxiety disorder (Elliott and Shahar 2017), and generalized anxiety disorder (Timulak and McElvaney 2015). There is also growing evidence of its application with couples for interpersonal/relational problems (Johnson and Greenberg 1987) and Emotion-Focused Family Therapy (EFFT) with

patients suffering from anorexia and eating difficulties (Dolhanty and Greenberg 2007). To date, positive preliminary findings for EFT-AS have been reported (Robinson and Elliott 2016) with a number of case conceptualization from clinical data of clients working through specific presenting problems, such as misempathy (Robinson and Elliott 2017), trauma-related experiences (Robinson 2018), and relational rupture and repair (Robinson 2019).

Outcome Measurement

CEPS-AS: Client Emotional Processing Scale for Autism Spectrum (Robinson and Elliott 2016)

CORE-10: Clinical Outcomes in Routine Evaluation

QCAE: Questionnaire of Cognitive and Affective Empathy (Reniers et al. 2011)

EQ: Empathy Quotient (Baron-Cohen and Wheelwright 2004)

HAT: Helpful Aspects of Therapy Form (Llewelyn et al. 1988).

TAS-20: Toronto Alexithymia Scale (Parker et al. 2003)

OHQ: The Oxford Happiness Questionnaire (Hills and Argyle 2002)

Qualifications of Treatment Providers

EFT-AS can be provided by (a) experienced autism practitioners with a master's degree in Autism Studies and successful completion of Counseling Skills in Autism Spectrum module and (b) qualified person-centered counselors/therapists or clinical psychologists with advanced Empathy Training and successful completion of a Autism Spectrum module. This provides basic skills training in the person-centered approach and theory of autism processing differences. Additional EFT-AS training provides basic teaching on setting up and running groups, which consists of learning how to analyze and edit video recordings, how to present IPR clips, and how to recognize task markers to introduce therapeutic deepening and enactment tasks.

Empathizing-Systemizing Theory

► Systems Intervention

Empathy

Nurit Yirmiya and Ifat Seidman
Department of Psychology, The Hebrew
University of Jerusalem, Jerusalem, Israel

Definition

Empathy, the capacity to share the feelings of others, is considered a significant core ability in the development of social and emotional

functioning. In general, individuals with autism experience difficulties in their capacity to empathize, thus failing to successfully engage in social interactions (Charman et al. 1997; Jones et al. 2010; Yirmiya et al. 1992).

In everyday language, as well as in the research literature, the term empathy is used synonymously for both mental and emotional states. However, cognitive empathy pertains to the capacity to represent others people's thoughts, beliefs, and intentions, whereas emotional empathy is defined as experiencing what it feels like for another person to experience a certain emotion, including a bodily sensation. Both indices tap overlapping processes and are considered interrelated aspects of the same complex construct of empathy (Singer 2006). Yet, there are quantitative differences. For example, sharing a close friend's feelings of grief is felt much differently than the recognition or comprehension of this person's thoughts and feelings in this painful situation. Understanding of these differences has led to the establishment of a more multidimensional approach to the definition of empathy, acknowledging that all these aspects are separate but related constructs of the integral concept of empathy (Eisenberg et al. 2006).

Sharing feelings with others may be manifested in facial and/or vocal expressions or in body movements and gestures. People can feel empathy for others in a range of emotional contexts, from basic sensations such as sadness or joy to more complex emotions such as love and remorse. Empathy has a variety of definitions such as the ability to place oneself in another's place ("put oneself in another's shoes"), the experiencing of another's affective or psychological states, or one's emotional responses to the emotional displays of others (Eisenberg and Fabes 1990; Moore 1990; Zahn-Waxler et al. 1992). Additional definitions describe empathy as an affective response more appropriate to someone else's situation than to one's own situation, or when another person's emotion evokes an analogous affective experience in oneself (Eisenberg et al. 2006). It is important to note that although in empathizing one may "feel the same" as another, the affective states of the self and other are nevertheless distinguishable. That

is, the emotion that was induced in the self by the perception of the other's emotional state can be distinguished from the same feeling originating in oneself. A related concept to empathy is sympathy, which is similarly described as an emotional response of sorrow or concern toward someone in distress. Sympathy usually stems from empathy, yet both empathy and sympathy differ from personal distress, which is a self-focused and somewhat aversive reaction of anxiety in response to a similar emotional state of distress in another (Eisenberg et al.).

The concept of empathy plays a significant role in developmental social cognition theories such as theory of mind (ToM) and the empathizing-systemizing theory and is associated with concepts such as mind reading, mentalizing, and perspective taking (Baron-Cohen 1995, 2002; Frith 1994). These theories suggest that the characteristic deficits in mentalizing skills that are associated with poor interpersonal relationships hinder the ability of individuals with autism to understand and engage in interpersonal relationships. In order to engage in reciprocal social interactions and to successfully navigate social exchanges, one should possess the capacity to recognize and accurately interpret and predict what the other is thinking and feeling and how he or she might respond.

Historical Background

In their initial writings, Leo Kanner as well as Hans Asperger described autism as affective impairment pertaining to difficulties in social and communicative functions as well as to difficulties in empathy. Kanner described "children's inability to relate themselves in the ordinary way to people and situations from the beginning of life." He noted that "It is not a 'withdrawal' from formerly existing participation. There is from the start an *extreme autistic aloneness* that whenever possible, disregards, ignores, shuts out anything that comes to the child from the outside" (Asperger 1944; Kanner 1943; Wing 1981). In his description, Asperger specifically addressed "autistic psychopathy" of children who manifested "severely disturbed and considerably

limited interaction. . . . and characteristic difficulties of social integration" including patterns of lack of empathy and difficulties in "reading between the lines."

Empathy is long considered an important process known to facilitate interpersonal relationships, particularly prosocial behavior. Religious, philosophical, and psychological theories have long debated whether humans are basically good, empathic, and altruistic in nature or whether all prosocial actions essentially derive from underlying egoism and self-interest. Twentieth century psychological theories such as Freud's psychoanalytic theory viewed human development mainly as an interplay between two innate trends, "egoistic" and "altruistic," although later psychoanalytic theories acknowledged prosocial actions as defense mechanisms used to deal with irrational demands such as feelings of guilt, self-destructive tendencies, and sexual strivings – all believed to underlie altruism and empathy. These theories also put forward the importance of the early mother-child relationship for the development of empathy, through mental mechanisms of identification and internalization. Furthermore, contemporary psychoanalytic theories consider empathy as crucial to the development of insight, for people may come to see themselves through eyes of others via empathy. Empathy is also considered an important condition for effective therapeutic intervention in psychotherapy. Piaget's theory on cognitive development emphasized the transition from infants' egocentric orientation to the more social orientations characteristic of later periods, through the acquisition of perspective-taking abilities during the preschool years; thus, prosocial behaviors were assumed to emerge at the beginning of the school years (Eisenberg et al. 2006).

Current Knowledge

Empathy in Individuals with Autism

A considerable body of research investigated difficulties in empathy among individuals with autism, who are characterized by qualitative impairments in social interaction and communication (Baron-Cohen and Wheelwright 2004;

Charman et al. 1997; Jones et al. 2010; Kasari et al. 2001; Rogers et al. 2007; Shamay-Tsoory et al. 2002; Yirmiya et al. 1992). It was suggested that individuals with autism exhibit deficits in their capacity to mentalize and empathize and that these core deficits hinder them in developing adequate reciprocal interactions. Individuals with autism reveal difficulties in interpreting social cues and in “mind reading” of others’ emotions; hence, it is more difficult for them to achieve a clear and accurate understanding of what other individuals think, feel, and experience.

Clinical observations suggested that children with autism do not respond to other people’s affect in the same way as children with typical development or children with mental retardation (Sigman and Capps 1997). The empathic response to negative affect (distress of other) was investigated in children with autism in comparison to children with typical development and children with mental retardation, matched on mental age (Kasari et al. 1993). It was found that more children with autism ignore, or did not notice, the negative affect of the adults and appeared less concerned than the other children in response to distressed adult. It was suggested that children with autism lack the cognitive and affective prerequisites that are necessary for being attentive and empathic to the emotion of others. Other studies investigated difficulties in the capacity to empathize in high-functioning children with autism and adolescents compared to typically developing children at the same age (Yirmiya et al. 1992). Children’s ability to discriminate between different emotional states, perspective-taking abilities of emotional states, and emotional responsiveness were compared. The strong associations between cognitive abilities and empathy that was found in the autism group compared to the typical development group may have suggested that children with autism use their cognitive abilities and cognitive strategies to successfully understand and engage in social situations more than is necessary for children with typical development (Sigman and Capps 1997).

Individuals with autism present difficulties in understanding the feelings and perspectives of

others, labeling the emotions felt by others, and responding with empathy. They also react unexpectedly to interpersonal situations. It is important to note that although individuals with autism manifest difficulties in empathy, this does not mean that their behavior in real-life situations is cold or uncaring or that their lack of empathy is related to antisocial behavior (Jones et al. 2010; Rogers et al. 2007). Many individuals with autism appear to show as much warmth, compassion, caring, and concern for others as typically developing individuals, especially when the information is presented in a way that allows them to better understand the feelings and perspectives of others. An alternative explanation for the lower empathy levels reported in autism than in typical development may be that these research findings could reflect difficulties in articulating emotions rather than in feeling them. Evidence for this possibility may be that individuals with autism who exhibit greater self-awareness as well as higher cognitive and verbal abilities are able to report their feelings more accurately and thus to appear more empathic than individuals with autism with lower cognitive and verbal abilities who exhibit lower levels of self-awareness and who show difficulties articulating their emotions (Travis et al. 2001; Yirmiya et al. 1992). Furthermore, comparing boys with autism and boys with psychopathic tendencies revealed that the latter had significant impairments in emotional empathy with intact perspective-taking abilities, whereas the boys with autism had a reverse pattern – significant impairments in cognitive perspective-taking abilities and intact emotional empathy (Jones et al. 2010).

Recently, Simon Baron-Cohen introduced the extreme male brain (EMB) theory of autism (Baron-Cohen 2002), suggesting that individuals with autism may manifest an exaggerated male brain psychometric profile, demonstrating extreme properties in two psychological dimensions: extremely low empathizing (defined as the drive to identify another’s mental state and to respond with an appropriate emotion) and extremely high systemizing (defined as mechanistic thinking; the drive to analyze, explore, and construct a system in terms of its underlying regularities).

The Development of Empathy

It is well known that infants and toddlers are sensitive and responsive to emotional cues or signals of others, thus yielding behaviors that resemble empathic expressiveness. An infant's reflexive crying or arousal-containing sucking behavior in response to the crying of another infant are considered early precursors of empathic reactivity (Ungerer et al. 1990; Zahn-Waxler et al. 1992). This emotional contagion, or emotional resonance, refers to the infant's ability to imitate another's emotional distress, without awareness of the other, and therefore is not considered "true" empathy. This kind of emotional involvement, which is strongly linked to infants' early developmental and cognitive abilities, diminishes after the first year as differentiation between self and other increases and toddlers come to perceive themselves as separate beings. Thus, empathy emerges throughout the second year of life, as well as sympathetic concern and comforting behaviors in response to others' distress (Eisenberg and Fabes 1990; Zahn-Waxler and Radkeyarrow 1990; Zahn-Waxler et al. 1992).

Longitudinal studies revealed that empathic behaviors increase and become more sophisticated and explicit during the first years, and this increase is associated with the developmental changes that are prerequisites for empathy. These cognitive and emotional prerequisites are self-other differentiation, perspective-taking ability, and emotion regulation, as well linguistic ability and social engagement skills. All these skills are necessary for the child to empathize, comfort others, inquire about others' feelings, and provide others with adequate support (Knafo et al. 2008; Zahn-Waxler et al. 1992). Furthermore, secure attachment relationships and early parent-infant interactions contribute to later development of empathy, through the synchronized exchange of shared emotions ("the dance") between the parents and infant in the first year. In the second year, emotion regulation pertains to the capacity for role-taking and the emergence of higher-order self-conscious emotions such as guilt or shame as well as empathy. Socialization and environmental influences also play an important role in the second year, when parents already expect their

children's behavior to be socially and interpersonally appropriate (Eisenberg et al. 2006).

Although the observation of early empathic manifestations in infants and toddlers is not straightforward due to children's limited verbal skills, some researchers demonstrated the presence of different early manifestations of empathic behaviors (Zahn-Waxler and Radkeyarrow 1990; Zahn-Waxler et al. 1992). For example, toddlers older than 1 year who observed a peer or adult in distress revealed varying behaviors: Some toddlers became quiet and observed the situation with a concerned facial expression; others expressed their discomfort by disquiet and agitated behaviors; and others ignored the distressed person and continued with their own activities. The earliest empathic reactions are mostly physical in nature, such as hugs and pats. After age 2 years, toddlers reveal more explicit empathic and prosocial behaviors such as verbally comforting, reaching for someone to get help, giving a victim toys, or trying to find ways to cheer someone up. Some of these behaviors may be still egocentric in nature; young children may try to comfort the other with things that make them feel better. With age, as ToM abilities become more developed (regarding the differentiation between one's own and others' states of mind) and as affective arousal becomes more modulated, children's empathic and prosocial behaviors become more attuned to the other person's needs (Eisenberg et al. 2006). There is some evidence regarding sex differences in empathy in the preschool years as well as in adulthood. Girls usually reveal more empathic reactions than boys, such as concern and joining into the emotional experiences of others, and these sex differences are present as early as 14 months. It may be assumed that these differences reflect both biologically based predispositions as well as socialization influences for females to be responsive to the physical and emotional needs of others (Eisenberg et al.).

Not many studies have investigated children with autism in terms of the emergence of empathy in the first years and the early manifestations of sympathetic concern and comforting behaviors in response to others' distress (Yirmiya et al. 1992),

as well as developmental trajectories for the ability to empathize in children with autism. Twenty-month-old toddlers with autism had difficulties looking to other person's face and showing expressed facial concern in response to feigned distress compared to control groups of 20-month-old toddlers with developmental delays and typical development (Charman et al. 1997). In a recent prospective study of young siblings of children with autism – a group considered at higher risk for autism – infants later diagnosed with autism paid less attention and showed less affective response to the examiner's display of a distress reaction as early as 12 months of age compared to infants who were not later diagnosed with autism (Hutman et al. 2010). Furthermore, it was found that atypical response to another person's distress differentiated infants subsequently diagnosed with autism from those infants who were not later diagnosed with autism spectrum disorder at 36 months. Thus, it was suggested that low levels of responsiveness to another person's distress at 12 and 18 months are indicative of elevated risk for autism spectrum disorder at 36 months. These findings need to be replicated in other low-risk and high-risk infant populations.

Measuring Empathy

Several research instruments have been used to measure empathy in children and adults in general and in individuals with autism. The Feshbach and Powell Audiovisual Test for Empathy (Feshbach 1982) was designed to measure children's empathy and emotional responsiveness. It consists of 10 videotaped segments presenting short stories about children experiencing different events and emotions such as happiness, anger, or sadness (e.g., a boy is sad because he lost his dog). After watching each story, the child is asked to report how he or she feels. In some adaptations of this procedure (Yirmiya et al. 1992), usually when examining children with autism, participants are first asked about the nature of the protagonists' feelings (labeling the emotion) in addition to the nature of their own emotional response to the video vignette (empathic reaction). This adaptation prevents the examiner from identifying children as failing to empathize in cases when the

child recognizes and reports a different emotion from the target emotion yet reveals the capacity to refer to the protagonist's emotional state.

Marian Sigman and her colleagues designed specific research procedures for measuring empathy among young children with autism (Sigman et al. 1992). The researchers recorded and then coded the child's reactions to a distress situation that was enacted by the mother. In this enactment, after a short period of play with a wooden pounding toy and hammer, the mother pretended to hurt herself by hitting her finger with the hammer, and she displayed facial and vocal expressions of distress without using words. Children with autism tended to ignore or not notice adults showing these negative affects more often than children with mental retardation or children with typical development.

Carolyn Zahn-Waxler and her colleagues (Zahn-Waxler et al. 1992), who investigated the early development of empathy in children and twins, used similar procedures where both an experimenter and the mother presented simulated situations of distress such as bumping into a chair. In addition, they used mothers as systematic observers, training them to collect data regarding their child's responses to the emotions of others, emotions both caused and witnessed by their children. This methodology may be of interest to investigators to employ in future studies of empathy in children with autism.

Children's limited verbal ability precludes the use of self-report measures, which are more common in the examination of empathy in adolescents and adults. The Interpersonal Reactivity Index (IRI; Davis 1983) is a self-report measure of empathy comprising four subscales: perspective-taking, empathic concern, personal distress, and fantasy. Although some of these subscales may not directly assess emotional empathy, indices such as imagination or emotional self-control correlate with empathy. A more recent self-report instrument for measuring empathy is the 60-item Empathy Quotient questionnaire (EQ; Baron-Cohen and Wheelwright 2004). This scale includes items like: "It is hard for me to see why some things upset people so much" or "I find it easy to put myself in somebody else's shoes" and

thus may be measuring prosocial behaviors and social skills in addition to empathy. Adults with Asperger's syndrome or high-functioning autism scored significantly lower on the EQ than individuals with typical development matched for age and sex; in addition, in the typical development group, women score significantly higher than men. Assessing individuals' beliefs about their own empathy might differ from their actual empathic reactions to emotional situations. Indeed, it is an important methodology strength of developmental research over the report measures used with older individuals.

Current Knowledge

Recent longitudinal and twin studies have identified continuity in empathic development over time and the relationship between empathy and prosocial behavior (Knafo et al. 2008). It was suggested that empathy is a relatively stable disposition across both time and different contexts, with heritability that tends to increase with age. Yet, environmental factors such as parenting practices, peer and sibling relationships, and educational programs contribute to empathic abilities (Knafo and Uzefovsky 2012). Several biological and genetic mechanisms were proposed as relevant to the development of empathy. Empathy was found to be associated with temperamental characteristics: For example, inhibited and unreactive temperament features in the first year were negatively associated with empathy at the age of 2 years (Young et al. 1999). Other studies have focused on the neuronal correlates and neural mechanisms underlying the ability to understand the mental and emotional states of others (Blair 1999; Singer 2006). Different neural circuitries were associated with the cognitive and emotional aspects of empathy: Perspective-taking abilities were found to involve structures of the superior temporal sulcus and the medial prefrontal cortex, whereas emotional empathy involved sensory-motor cortices as well as limbic and paralimbic structures (the "social" or "emotional" brain). Moreover, it was found that the limbic structures develop earlier than the temporal lobe and prefrontal structures – in line with developmental studies that demonstrated the early

precursors of emotional empathy during the first year as well as the later emergence of cognitive perspective-taking abilities (Decety 2010; Singer 2006).

Some speculations were raised about the associations between empathy and autism and the network of visuomotor cells known as mirror neurons (MNs). The MNs are activated and discharged when the individual performs a particular motor action as well as when observing somebody else perform a similar action. Thus, it was suggested that the MNs as an execution/observation matching system may be connected to social and emotional functioning such as imitation and empathy, which are considered as impaired in autism (Perkins et al. 2010). Finally, molecular genetics studies have demonstrated the associations between social behavior and two non-a peptides of arginine: vasopressin and oxytocin (Israel et al. 2008; Yirmiya et al. 2006). It was suggested that the arginine vasopressin receptor 1a (AVPR1a) gene and the oxytocin receptor (OXTR) gene are possible contributors to altruistic behavior. Furthermore, family studies of individuals with autism and their relatives revealed the role of the AVPR1a gene in mediating the association of socialization skills in autism. Other genetic studies examined candidate genes in a group of individuals with Asperger's syndrome and a population sample. Nineteen genes showed nominally significant associations with self-report measures of empathy (Empathy Quotient questionnaire) and autistic traits (the Autism Quotient questionnaire) (Chakrabarti et al. 2009).

Future Directions

Although difficulties in empathy are detectable among individuals with autism, not much is yet known about the developmental trajectories of empathy in infants or toddlers who are later diagnosed with autism (Hutman et al. 2010). The search for empathy precursors in autism is closely linked to the investigation of early manifestations of autism in the first year/s of life. Future research would do well to track infants who are underresponsive to emotional cues such as others'

distress and to explore these infants' developmental trajectories and later diagnoses. It will be of great importance to know whether early underresponsiveness during the first year predicts future diagnoses of autism or other developmental difficulties. Furthermore, within the field of autism, treatment studies should be initiated to explore strategies to improve the capacity to empathize and thus to facilitate the various aspects of social interactions and relationships.

Empirically Supported Treatments

Brian Reichow

Child Study Center, Yale University School of Medicine, New Haven, CT, USA

Anita Zucker Center for Excellence in Early Childhood Studies, University of Florida, Gainesville, FL, USA

Definition

Evidence-based practice (EBP) refers to a multi-step process used to make decisions that involves the appraisal of current evidence, reference to clinical expertise, and consideration of patient values and choice (Sackett et al. 1996).

Historical Background

The conceptualization, ideals, and guidelines that have become evidence-based practice (EBP) emerged first in the medical field as evidence-based medicine. EBP is a multistep process that involves the appraisal of current evidence, reference to clinical expertise, and consideration of patient values and choice (Sackett et al. 1996). Since moving to the social sciences, EBP, albeit under various names (e.g., empirically supported treatment, scientifically based research), has been further refined and expanded to match the ideologies and traditions of the various disciplines within the social sciences. Most organizations representing individuals practicing in the social sciences now have a definition of EBP, although the amount and type of evidence needed for a practice to be recognized as evidence-based often differ across organizations. Given the

multitude of disciplines working in the field of autism, this likely hindered early efforts at identifying EBP.

Current Knowledge

Recently, a number of practices and treatments for individuals with ASDs have been identified EBP. Two recent books (e.g., *Evidence-Based Practices and Treatments for Children with Autism* (Reichow et al. 2011) and *Effective Practices for Children with Autism* (Luiselli et al. 2008)) have shown that many autism treatments can now be considered evidence-based (see also *Educating Children with Autism*; National Research Council 2001). Evidence of EBP in autism in peer-reviewed publications has also emerged. In 2000, Filipek and colleagues applied the American Academy of Neurology standards to screening and diagnostic procedures, and Rogers and Vismara (2008) outlined the evidence for autism treatments for the 10-year follow-up of APA Division 53 assessment of EBP. The new report suggested early intensive behavioral intervention based on applied behavior analysis, pivotal response treatment, and parent education could now be considered evidence-based. Shortly thereafter, two independent comprehensive reviews by the National Professional Development Center on ASD (2008) and the National Autism Center (2009) identified dozens of focal treatments that are evidence-based, including, but not limited to, visual schedules, social narratives, prompting, and reinforcement (complete lists available at websites listed below). Updates to both of these guides is currently underway which should further our knowledge about the most effective treatments for children with ASD. Government-led health agencies (e.g., Agency for Healthcare Research and Quality 2011; National Institute for Health and Clinical Excellence 2011; Scottish Intercollegiate Guidelines Network 2007) have also issued guidelines, often with accompanying parent-friendly guides, thus helping ensure consumers are able to access this critical information necessary to be an active participant in the EBP process.

Future Directions

The amount of research on ASD continues to expand. Thereby, continued identification of EBP for individuals with ASDs will be needed. Currently, little is known a priori concerning which EBP will be the most successful treatment for specific individuals. Future EBP guides should strive to help identify the individual characteristics of the client, therapist, and/or setting that will help maximize outcomes. Given the research to practice gap, further dissemination of EBPs are also needed, especially in formats that are accessible to practitioners and parents. As society continues to expand its use and emphasis of technology, it will also be important to begin to understand how the World Wide Web and social media (e.g., Facebook, Twitter) might be utilized to disseminate EBP to parents and practitioners. Research has shown that parents utilize the World Wide Web more than any other source to gain information on ASD, but recent analyses of the quality of the information on autism websites suggest caution and vigilance are needed as consumers are likely to access sites with mixed or poor quality (Reichow et al. 2012).

Synonyms

[Employ](#); [Pay](#); [Service](#); [Working for pay](#)

Definition

An agreement between a person and a representative of a business who has hiring authority (i.e., owner, manager, personnel director, etc.) to exchange labor for a wage that is in alignment with others who are performing comparable work in the workplace and at least meets the federal minimum wage standard.

An arrangement where a person engages in providing a service and/or producing a product for another entity (person, the public, business, etc.) in exchange for monetary payment to earn a livable income.

Definition

There is limited research outlining the specific services and supports required by individuals with ASD. However, some examples of a supported employment approach have been described (e.g., Hillier et al. 2007a, b; Howlin et al. 2005; Keel et al. 1997; Lawer et al. 2009; Nesbitt 2000; Smith 1994; Schaller and Yang 2005; Wehman et al. 2009). Using this advocacy level service, a vocational rehabilitation professional known as an employment specialist or job coach provides and/or facilitates a unique mix of supports that vary in type, level, and intensity uniquely designed to assist the person with gaining and maintaining employment (Wehman et al. 2009).

Additionally, case studies conducted with adults with ASD provide tremendous insight regarding vocational needs (Hurlbutt and Chalmers 2002, 2004; Müller et al. 2003; Wehman et al. 2009). From this research, recommendations for vocational supports can be ascertained and grouped into four major themes: (1) job placement (Schaller and Yang 2005) and match (Howlin et al. 2005; Keel et al. 1997; Mawhood and Howlin 1999; Müller et al. 2003), (2) supervisors and coworkers (Bolman 2008; Burt et al. 1991; Hagner and Cooney 2005; Hillier et al. 2007a, b; Howlin et al. 2005; Keel et al. 1997; Mawhood and Howlin 1999; Müller et al. 2003; Nesbitt 2000), (3) on-the-job provisions (Burt et al. 1991; Fast 2004; Hagner and Cooney

2005; Hillier et al. 2007a, b; Lawer et al. 2009; Nuehring and Sitlington 2003; Smith et al. 1995), (4) work place modifications (Fast 2004; Hagner and Cooney 2005; Müller et al. 2003; Nuehring and Sitlington 2003) and predictability (Burt et al. 1991; Foley and Staples 2003; Hagner and Cooney 2005; Hume and Odom 2007), and (5) long-term support (Hillier et al. 2007a, b; Howlin et al. 2005; Keel et al. 1997; Müller et al. 2003; Smith and Philippen 1999; Smith et al. 1995).

While the small body of existing research gives shape to this topic, there are limitations. The number of peer-reviewed articles on this topic is scarce and hampered by limited sample sizes and restricted population ranges. Existing research covers an array of topics, yielding few solid conclusions in any given area. However, to some degree, the evidence does seem to endorse supported employment as a promising practice to assist individuals with ASD with employment and career advancement. If this supported employment is going to become a viable option for individuals with ASD, then key stakeholders including individuals with ASD, family members, educators, vocational rehabilitation service providers, and others will need to learn how to individualize an array of specific supports at work designed to meet each person's unique needs.

It will also require education of employers to understand how employing an individual with ASD can bring value to business. In summary, to date, few solid conclusions have been reached, and more research is needed.

Historical Background

There is limited research outlining the specific services and supports required by individuals with ASD. However, some examples of a supported employment approach have been described (e.g., Hillier et al. 2007a, b; Howlin et al. 2005; Keel et al. 1997; Lawer et al. 2009; Nesbitt 2000; Smith 1994; Schaller and Yang 2005; Wehman et al. 2009). coach provides and/or facilitates a unique mix of supports that vary in type, level, and intensity uniquely designed to assist the person with gaining and maintaining employment (Wehman et al. 2009).

Additionally, case studies conducted with adults with ASD provide tremendous insight regarding vocational needs (Hurlbutt and Chalmers 2002, 2004; Müller et al. 2003; Wehman et al. 2009). From this research, recommendations for vocational supports can be ascertained and grouped into major themes: (1) job placement (Schaller and Yang 2005) and match (Howlin et al. 2005; Keel et al. 1997; Mawhood and Howlin 1999; Müller et al. 2003), (2) supervisors and coworkers (Bolman 2008; Burt et al. 1991; Hagner and Cooney 2005; Hillier et al. 2007a, b; Howlin et al. 2005; Keel et al. 1997; Mawhood and Howlin 1999; Müller et al. 2003; Nesbitt 2000), (3) on-the-job provisions (Burt et al. 1991; Fast 2004; Hagner and Cooney 2005; Hillier et al. 2007a, b; Lawer et al. 2009; Nuehring and Sitlington 2003; Smith et al. 1995), (4) work place modifications (Fast 2004; Hagner and Cooney 2005; Müller et al. 2003; Nuehring and Sitlington 2003) and predictability (Burt et al. 1991; Foley and Staples 2003; Hagner and Cooney 2005; Hume and Odom 2007), and (5) long-term support (Hillier et al. 2007a, b; Howlin et al. 2005; Keel et al. 1997; Müller et al. 2003; Smith and Philippen 1999; Smith et al. 1995).

While the small body of existing research gives shape to this topic, there are limitations. The number of peer-reviewed articles on this topic is scarce and hampered by limited sample sizes and restricted population ranges. Existing research covers an array of topics, yielding few solid conclusions in any given area. However, to some degree, the evidence does seem to endorse supported employment as a promising practice to assist individuals with ASD with employment and career advancement. If this supported employment is going to become a viable option for individuals with ASD, then key stakeholders including individuals with ASD, family members, educators, vocational rehabilitation service providers, and others will need to learn how to

individualize an array of specific supports at work designed to meet each person's unique needs.

It will also require education of employers to understand how employing an individual with ASD can bring value to business. In summary, to date, few solid conclusions have been reached, and more research is needed.

Current Knowledge

Predicting outcome and planning for adult service needs for children with autism spectrum disorders (ASD) is limited by gaps in current knowledge. The best quality information about autism in adulthood comes from a few population-based longitudinal studies that estimate the full picture of outcomes. However, changes in diagnostic criteria in the 1990s from a comparatively narrow definition to the broader current criteria for ASD means that studies of adults originally diagnosed as children with historical criteria have limited application to later generations. In addition, longitudinal research that depends on information from aging caregivers has inherent challenges. For example, recall of symptoms from earlier life may be compromised by memory problems and health problems of the aging informant. An alternative research design using cross-sectional samples of adults diagnosed with current, broader criteria can provide data relevant to the future of children being diagnosed today. Such cross-sectional studies are useful adjuncts to population-based, longitudinal research as they give a more comprehensive understanding of ASD in adulthood and can bring focus to specific issues. For example, the prevalence and variety of behaviors that lead to encounters with law enforcement have been described by Allen et al. (2009).

Two useful prognostic factors for adult outcome in ASD are childhood intellectual ability and onset of communicative speech. Like other people with intellectual disabilities (ID), people with ASD and ID generally achieve a limited range of independence and "success" in adult life as defined in developed Western societies

inclusive of gainful employment, a household independent of their parents, and a circle of reciprocal friendships and romantic relationships. Those with average-range intellectual abilities (i.e., ≥ 70) have widely varying adult outcomes. Several longitudinal studies have demonstrated that communicative phrase speech before age 6 and an average-range childhood intelligence quotient (IQ) are necessary for a chance at adult independence but in no way guarantee it (Billstedt et al. 2005; Farley et al. 2009; Howlin et al. 2004; Kobayashi et al. 1992). When assessed in adulthood, barriers to independence in people with ASD and average-range intellectual abilities appear to include co-occurring psychiatric conditions, difficulty with initiation of goal-oriented activities, and poor social skills. There may also be specific genetic variations, developmental processes, educational opportunities, ecological factors, and specialized adult supports that influence levels of independence in adulthood.

Natural Course

While ASD is a lifetime diagnosis, several longitudinal studies have shown improvements in autistic symptoms over the lifespan (Billstedt et al. 2005; Cederlund et al. 2008; Piven et al. 1996; Rumsey et al. 1985; Seltzer et al. 2004). The trend is toward improvement in symptom severity in participants as a group, with the greatest amount of behavioral improvement in individuals who had the highest IQs and the least severe symptom presentation at the initial evaluation. These studies also show that a small proportion of affected individuals no longer meet full diagnostic criteria in adulthood. Importantly, most of these individuals retain subtle impairments that continue to present daily challenges to fully independent functioning.

There also appears to be a small subgroup that experiences significant deterioration in cognitive or behavioral functioning in adolescence (Ballaban-Gil et al. 1996; Kobayashi et al. 1992; Venter et al. 1992). Causes for this deterioration are unknown as yet, but appear unrelated to

adolescent seizure onset that occurs in some individuals with ASD.

Mortality

Studies of mortality in autism have identified a higher rate of mortality for populations with ASD than in the general population, owing largely to complications related to epilepsy and other medical conditions and to accidental deaths that may be associated with ID. Standardized mortality ratios (i.e., the ratio of observed deaths in a specific sample to expected mortality in the general population matched on variables such as age, gender, and length of follow-up period) range from 1.9 to 2.4, approximately twice the expected rate for the general population (Isager et al. 1999; Pickett et al. 2006; Shavelle et al. 2001). Females have had higher mortality rates than males in studied populations, probably associated with a higher rate of ID.

Selected Longitudinal Outcome Studies

A number of authors have categorized outcomes of adults with AD using broad social and educational or occupational criteria (Howlin et al. 2004). Outcome classifications usually include five nodes and range from Very Poor (i.e., the person cannot function independently in any way) to Very Good (i.e., achieving great independence, having friends and a job). Findings from outcome studies are quite disparate, in spite of considerable similarities between outcome criteria and samples. A consistent finding from published outcome studies is that outcome for a majority (approximately 60%) of individuals with ASD was Fair, Poor, or Very Poor (Billstedt et al. 2005; Eaves and Ho 2008; Howlin et al. 2004).

Gillberg and Steffenburg (1987) studied outcome for a population-based sample of 23 people with ASD. As children, one-third obtained IQ scores in the mildly mentally retarded range, and 26% achieved scores in the normal or near normal ranges. Eight (35%) had communicative speech at age 6. These 23 participants were aged

16–23 years at the time of the follow-up. One person (4% of the sample) obtained a “Good” outcome. Thirty-five percent experienced the “Fair, but restricted outcome” (i.e., characteristics of “poor” outcome status, but accepted by and included in some social community). Thirteen percent had a “Fair” outcome, and 44% had “Poor” or “Very Poor” outcomes. Childhood IQ and use of communicative speech at age 6 were useful predictors of outcome status. Epileptic seizures were present in one-third of the population, often associated with severe mental retardation and pubertal symptom aggravation.

Kobayashi et al. (1992) conducted a follow-up investigation of 201 adults identified with ASD in childhood through clinical services in Japan. Four of the people had died. The mean age for the remaining 197 young adults was 21 years and 8 months ($SD = 3.6$). About one-fourth of the sample had an IQ score of 70 or better at age 6, and about 20% were able to speak without echolalia at that age. An additional 31% used communicative language at age 6 but also used echolalic speech. Forty percent of the sample began school in a general education class, but only 27% remained in general education at the age of 12. At follow-up, 43 (21%) were employed and 11 (6%) were enrolled in higher education or vocational training programs. Outcome adjustment was “Good” or “Very Good” for 47%, was “Fair” for 32%, and was “Poor” or “Very Poor” for 46%. Childhood IQ was the only strong predictor of outcome in this investigation. Although there were similarities between the sample in this study and others reported, the outcome for these participants was strikingly better, overall. The authors provided some possible explanations including sociodemographic factors in Japan, advances in public education standards for people with disabilities, intensive intervention histories, and a high proportion of people with ASD and average-range IQ scores at baseline.

Howlin et al. (2004) studied adult outcome for 68 people with ASD who also had a childhood nonverbal IQ score of 50 or better. The mean age at the initial evaluation was 7.24 ($SD = 3.10$) and at follow-up was 29.33 ($SD = 7.97$). Nonverbal IQ scores averaged 80.21 ($SD = 19.28$). At

follow-up, the average nonverbal IQ was 75 ($SD = 21.52$). Almost all of the subjects were known to have attended compulsory schooling; however, only 22% left school having achieved formal qualifications. At the time of the follow-up investigation, 23 people were employed. Eight worked in regular, independent jobs, one was self-employed as an artist but was unable to earn a living wage, and 14 worked in sheltered or supported employment. Twenty-seven people were occupied in general work/leisure programs at day centers for adults with disabilities. Outcome adjustment ratings for the sample were that 22% had “Good” or “Very Good” outcomes, 19% had “Fair” outcomes, and 58% had “Poor” or “Very Poor” outcomes. Analyses of the assessment results revealed that childhood IQ was a useful predictor of adult adjustment in that those with childhood nonverbal IQ scores of 70 or more were more likely to do well than those with scores below 70. Furthermore, a score of 100 or better did not increase the likelihood that a person would do well in adulthood. For those who were capable of completing a childhood verbal IQ measure, the combination of verbal and nonverbal IQ scores in childhood provided a more precise indication of outcome classification, with scores above 70 in both domains yielding the greatest likelihood of a “Fair” outcome or better. Specifically, among those with childhood nonverbal IQ scores of 70 or more, 7 had a “Very Good” outcome, 7 had a “Good” outcome, 10 obtained a “Fair” outcome, and 20 had “Poor” or “Very Poor” outcomes. Language level at age 5 was useful in predicting overall outcome and residential status, but none of the other outcome variables studied demonstrated predictive utility.

Eaves and Ho (2008) followed 48 individuals with autism spectrum disorders from childhood (mean age = 6.8) to adulthood (mean age = 24) in Canada. Fifty-seven percent of this sample had autistic disorder, while the remainder had less severe variants of ASD. Eight of the participants had a childhood IQ score above 70. All participants received special education support during their compulsory schooling years, and 30% engaged in some kind of post-secondary educational program. Overall outcome adjustment

ratings were that 21% had “Good” or “Very Good” outcomes, 32% had “Fair” outcomes, and 46% had “Poor” outcomes. No participants fell within the “Very Poor” outcome categorization. Sixty percent of the sample resided at home with their parents, 19% lived in group homes, and 13% lived in foster care. Almost 80% received a government disability pension and used the services of social workers. In this sample, childhood verbal IQ was most predictive of outcome status. However, the proportion of individuals who were capable of completing an assessment of verbal IQ was not reported.

Also in Cederlund et al. (2008), Cederlund et al. released their study of outcome for 70 adults with autism and 70 adults with Asperger syndrome, after 5 or more years time elapsed from original diagnosis. This research team used the same outcome categorization scheme as Gillberg and Steffenburg (1987), with categories of “Good,” “Fair,” “Restricted,” “Poor,” and “Very Poor.” Twenty-seven percent ($n = 19$) of this sample obtained an outcome categorization of “Good,” and 47% ($n = 33$) were categorized as having a “Fair” outcome. Sixteen people, or 23%, obtained “Restricted” outcome status, and 2 people, or 3%, fell within the “Poor” category. There were no participants with “Very Poor” outcome ratings.

Farley et al. (2009) studied 41 adults who had been identified through a population-based study of ASD in Utah in the 1980s. All of these individuals had previous IQ scores of 70 or greater. Mean age at the first assessment was 7.2 years ($SD = 4.1$) and in adulthood was 32.5 years ($SD = 5.7$). Outcome adjustment was somewhat better for this sample than previous samples, with 48% in the “Very Good” and “Good” categories, 34% in the “Fair” category, and 17% in the “Poor” category. No participants fit within the “Very Poor” category of outcome categorization. Six participants did not meet diagnostic criteria for current ASD using gold-standard diagnostic procedures, but five of these still retained significant social difficulties reported by themselves or significant others. Half were employed on a full- or part-time basis, and 39% had attended some kind of formal post-secondary education. Over half of the

sample (56%) continued to live with their parents, and almost 25% lived in supported living arrangements including a state residential center for people with significant disabilities. Almost 60% of the sample reported co-occurring psychiatric diagnoses. Reported chronic medical conditions were those commonly seen in the general population (e.g., seasonal allergies, gout, high blood pressure).

Cognitive Function

Evidence to date reflects uneven development of cognitive abilities across people with ASD. Initial evaluations during childhood often indicate better nonverbal than verbal abilities. However, many studies show evidence increases in verbal ability and decreases in nonverbal ability during adolescence and adulthood. Group results for individuals with ASD and average-range IQ scores demonstrate consistency in the distribution of subtest scores on Wechsler scales. However, some individuals who have relatively high IQs in childhood demonstrate significant increases in overall ability at follow-up. Disparities among findings may have several causes. Selection of tests at initial evaluation and follow-up for their appropriateness to the research question and participants’ behavior may influence results. Furthermore, tests may not be sufficiently parallel for comparison so that some of the variance is attributable to inequality across measures. Variation of tests from the initial evaluation to follow-up further obscures results since within-group variation on measures may be considerable (Howlin et al. 2004). Age at initial IQ also appears to be an important factor, with nonverbal abilities varying more among children initially tested before age 5 (Howlin et al. 2004).

Associated Co-occurring Conditions

Many of the outcome studies concerning adults with AD provide information concerning co-occurring medical and psychiatric conditions. Few have analyzed the specific contributions

these disorders make to restrictions in overall outcome (Danielsson et al. 2005). One of the clearest indicators of the presence of significant co-occurring psychiatric and medical diagnoses is the proportion of individuals who are prescribed anticonvulsant and psychotropic medications. Eaves and Ho (2008) reported that 40% of their sample was prescribed medication for behavioral difficulties. Similarly, 40% of the participants in the population-based study by Billstedt et al. (2005) were prescribed medication for psychiatric disorders, and 40% of the adolescents and adults in another study were prescribed psychotropic medications to control behavior (Ballaban-Gil et al. 1996). Thirty-seven percent of those studied by Farley et al. (2009) were described as taking prescription medications aimed at managing behavioral difficulties.

Epilepsy is a chronic condition involving recurring seizures and is more common in individuals with ASD than in the general population, with an average prevalence rate of 16.8% across epidemiological studies of ASD (Fombonne 2005). This disorder occurs more frequently in individuals with ASD and ID. The onset of seizures typically occurs early in childhood (i.e., before age 2) or in adolescence (Danielsson et al. 2005; Kobayashi et al. 1992). Seizures remit in a fraction of those afflicted (Danielsson et al. 2005). Kobayashi et al. (1992) reported that 19% of their sample, representing the full range of functioning within ASD, had epilepsy, and all took anti-epileptic medication. Nine percent of a sample of adults with ASD and average-range IQ scores who were taking antiepileptics (Howlin et al. 2004).

Affective disorders challenge a person's capacity to regulate mood and include depression, mania, and bipolar disorder. It is estimated that over 60% of people with AD suffer from a co-occurring affective disorder. In a study of 35 individuals with Asperger syndrome, Ghaziuddin et al. (1998) found that affective disorders were the most common type of psychiatric condition co-occurring in adults, affecting over half of their sample. Figures from outcome studies with adult samples range from 1% to 30% (Billstedt et al. 2005; Farley et al. 2009).

Results of several outcome studies demonstrate that anxiety disorders are present in a large proportion of adults with AD. Rumsey et al. (1985) determined that 50% of their sample was suffering from chronic, generalized anxiety which they suggested could account for the attention difficulties observed in one fifth of the sample. Another study of adults with ASD and average-range IQ scores concluded that 40% of their sample had OCD or chronic anxiety. Figures from other outcome studies are much smaller; however, these results may be confounded by the presence of ritualistic characteristics and hyperactivity commonly associated with ASD (Ghaziuddin et al. 1998).

Hyperactivity and short attention span are common in people with ASD. These have been most commonly noted in children, yet some adults present with behavioral characteristics of attention deficit-hyperactivity disorder (ADHD) as well (Ghaziuddin et al. 1998). Forty (33%) of the adults in the study by Billstedt et al. (2005) presented with hyperactivity.

Psychiatric conditions evident in a small number of people with ASD include tic disorders, psychotic features, and catatonia. Almost 20% of the sample examined by Billstedt et al. (2005) demonstrated tics, and 10% of the adults studied by Eaves and Ho (2008) had Tourette's disorder. One of the 15 adults in another investigation presented with Tourette's disorder (Ghaziuddin et al. 1998). A small number of individuals with ASD genuinely have co-occurring psychotic conditions. Eight percent of the sample in the study of adults with ASD conducted by Billstedt et al. (2005) and 38% of those examined by Szatmari et al. had characteristics of psychosis. Catatonia is another type of psychiatric disturbance that is rarely observed, but notable, in ASD. One of the 15 adults studied by Howlin (2000) had a sudden-onset catatonic episode during puberty. Billstedt et al. (2005) reported a much higher percentage (12%) in their sample of 120 adults.

While not psychiatric disorders in their own right, maladaptive behaviors are significant deviations from expected behavior for a person's developmental level. They are often disruptive and sometimes dangerous. Maladaptive behaviors

are frequently observed in people with ASD of all levels of ability and developmental age. In general terms, maladaptive behaviors have been reported in up to 69% of adults with ASD with no overall difference in frequency between males and females (Ballaban-Gil et al. 1996; Eaves and Ho 2008). Maladaptive behaviors may be relatively infrequent in adults with ASD and average-range IQ scores, but odd or severe enough to preclude acceptance into general social settings over time (Rumsey et al. 1985). Self-injurious behaviors were reported to have occurred in 50% of the sample studied by Billstedt et al. (2005) and have been reported to be more common in females than in males (Ballaban-Gil et al. 1996). Difficulties with toileting and feeding appear to persist in lower-functioning individuals, but difficulties with compulsive rituals may develop around these tasks in higher-functioning adults as well. Aggression among adults is rarely designed to harm others, but property damage or harm to self may occur intermittently, sometimes in response to unimportant changes or problems in the environment (Rumsey et al. 1985).

Social Relationships

Few adults with ASD develop significant relationships outside of the family of origin in spite of common increases in interest in developing social relationships as individuals with AD age (Rumsey et al. 1985). Almost 75% of family members interviewed in the study by Eaves and Ho (2008) reported that they enjoyed good to excellent relationships with their affected relative; however, only one-third of the sample of affected adults had one or more friendships outside of the family. Similar results have been found in other studies of adults with ASD (Howlin et al. 2004). Females have reportedly experienced greater success with peer relationships than males (Piven et al. 1996). Ten percent of adults in the study by Eaves and Ho (2008) had a romantic relationship at some time in the past, but none of the participants were romantically involved at the time of the investigation. Nineteen percent of the men with Asperger syndrome disorder in the Cederlund et al. (2008)

study and 3% of the men with autistic disorder were or had been in long-term romantic relationships. Thirty-two percent of those studied by Farley et al. (2009) had dated, and 20% were involved in a serious relationship at the time of the study. In general, very few adults with ASD have been reported to have successful, long-term romantic relationships (Howlin et al. 2004).

Education and Employment

Approximately 15% of adults with ASD studied in outcome research attend post-secondary education programs (Ballaban-Gil et al. 1996; Farley et al. 2009; Kobayashi et al. 1992; Rumsey et al. 1985; Venter et al. 1992). In general, gainful employment for adults with ASD is rare, as is sheltered employment, occupying less than 40% of adults with AD (Howlin et al. 2004). While outcome studies of autism into adulthood conducted since 1992 reflect some steady improvements in employment rates, with 22–54% of participants reporting gainful employment on a full- or part-time basis (Ballaban-Gil et al. 1996; Farley et al. 2009; Howlin 1994; Kobayashi et al. 1992; Venter et al. 1992), many of these individuals are underemployed based on their cognitive abilities and academic credentials.

Forensic Problems

Involvement with police officers and other law enforcement agents has been recognized as a major concern for parents of adolescents and adults with ASD. A study of offending behavior in 33 individuals with Asperger syndrome (Allen et al. 2009) revealed that most engaged in violent or threatening behavior that was related to interpersonal problems including social or sexual rejection, bullying, or family conflict. Investigators have suggested such offending behavior was likely to result from coercion by others, misinterpretation of social situations, or obsessional interests, while many with ASD may be protected from these by their tendency to adhere strictly to rules. Allen et al. (2009) found evidence of this insight

in that the least common offenses identified among their population of offenders with Asperger syndrome were drug offenses, theft, fraud, sexual offending, and motor offenses. Cederlund et al. (2008) found that 10% ($n = 7$) of their sample with Asperger syndrome had been involved with law enforcement officers, but the remainder was described as very law abiding. None of the individuals in their lower-functioning sample with autistic disorder had committed legal offenses. In the study by Farley et al. (2009), 29% of the sample was involved with law enforcement offices for infractions after childhood, but these were related exclusively to “suspicious” behaviors deriving from special interests, participants being coerced to engage in antisocial behavior by peers, and social misunderstandings.

Future Directions

The prognosis for a majority of adults with ASD based on studies conducted to date is guarded. Future studies are needed to further define the subtypes of ASD and the factors that influence adult outcome. Studies of genetics, brain imaging, and responses to interventions are likely to yield important information.

Definition

Work has a central role in adult life. Employment integration can fulfill a variety of needs, from basic subsistence, through social inclusion, to an expression of personal interests, abilities, self-concepts and values (Blustein 2013). Although employment of adults diagnosed with autism spectrum disorder (ASD) has received growing attention and effort, outcomes in this field remain unsatisfactory. In aim of taking the field foreword, new theoretical perspectives can shed more light on labor market integration of adults with ASD. We suggest that the self-determination theory (SDT) of motivation (Deci and Ryan 2000) has the potential to expand our knowledge and inform vocational rehabilitation practice.

Historical Background

In view of the growing prevalence of ASD, more and more diagnosed individuals face the transition from childhood and adolescence into adulthood, which presents new, complicated challenges. Concurrently, research looking into adult outcomes is growing in number and in breadth. The last decades have seen transition in the conceptualization of successful adult outcomes for individuals with ASD, with outcomes becoming more specific and measures more valid and reliable. As part of this change, employment has become a specific outcome criterion in adulthood (Henninger and Taylor 2013). Hence, the history

of autism and employment in research and practice is relatively young, and the road to successful employment is still considerably unpaved.

Looking at the literature up to the present time, three main research directions are evident: evaluations of employment outcomes; conceptualizations of strengths and barriers to work; and assessments of interventions, aiming to point out what elements promote success.

Many studies quantify employment outcomes of adults with ASD, in comparison to the general population and to other clinical groups. Overall, results show high rates of unemployment, unfavorable job conditions for those who do work, and a relatively high prevalence of “overeducation,” representing the gap between educational attainments and actual jobs (Baldwin et al. 2014). Outcomes are unfavorable not only in comparison to the general population but also to other disabilities (Chen et al. 2015).

A second body of knowledge is directed at defining common work-related strengths and challenges. Many studies have been devoted to this objective, examining perspectives of employees, employers, and other stakeholders involved, such as parents and vocational rehabilitation practitioners. The picture known to us today is quite detailed and consistent across studies. Challenges that frequently arise when facing employment are related to communication and social deficits, cognitive functions (specifically impairments in executive functions), and difficulties modulating sensory stimuli. These various difficulties can be a constant source of stress and anxiety, which also pose a central obstacle for individuals with ASD who seek employment (Chen et al. 2015; Hendricks 2010).

Alongside the challenges, there are also unique characteristics that may give individuals with ASD an advantage in the work domain. Research lists advantages such as enhanced visual search abilities, a preference for detail-oriented tasks, and a systematic working style (Chen et al. 2015; Hendricks 2010). Characteristic “special interests” have been also suggested to lead to expertise that can form an advantage in certain fields (Winter-Messiers 2007). Moreover, employers of workers with ASD reported

favorable personal characteristics such as punctuality, devotion, and consistency, which are perceived as contributing to work performance (Scott et al. 2017).

Last, in an attempt to overcome barriers to employment, interventions aimed at promoting employment integration were developed. Programs answering the needs of adults with ASD have been documented for over a decade. These target the common obstacles described above and apply different strategies for success. Commonly, the curriculum includes improving social and executive skills. Interventions offer work placement along with personalized supports and accommodations (Hedley et al. 2017). These practices seem promising, as research results show good outcomes. However, there is still a long way to go in means of the quality of research being done and the ability to generalize and disseminate research findings for the benefit of successful inclusion of the wide population of adults with ASD in the vocational world.

Current Knowledge

Two notable trends are prominent in the literature in recent years. The first widens the scope beyond the personal characteristics of the individuals seeking employment and suggests environmental accommodations are also obligatory. A focus on finding a fit between the person, the job, and the occupational surrounding is becoming more and more prominent. Success is no longer considered solely the responsibility of the individual, and the environment is also expected to adjust (Scott et al. 2019; Waisman-Nitzan et al. 2018). In addition, it is becoming clear that the key to success involves cooperation of multiple stakeholders (Nicholas et al. 2018).

The second trend, aligned with the neurodiversity movement, encourages organizations to accept workers with ASD and benefit from the unique characteristics and skills they may bring to the job. This strength-based approach emphasizes the need to highlight ASD-related strengths that can be relevant to the labor market. A common expression of this approach

can be found in the suggestion that characteristic “special interests” can be used to promote labor market integration (Winter-Messiers 2007; Kirchner and Dziobek 2014). This approach has been complimented by cultural trends, portrayed in the media and through anecdotal autobiographical accounts of individuals with autism. These cases demonstrate how a special interest in a specific field, matched with high abilities, can lead to a successful career (Grandin 2006). This potential match has been discussed in the field but has not been systematically studied (Harrop et al. 2019). The feasibility of using this approach in a wider population of adults with ASD seeking employment has been questioned (Goldfarb et al. 2019) and requires further investigation.

Without underestimating the importance of promoting workplace diversity, the reality of the labor market holds expectations for performance, productiveness, and profitability. Hence, a creative and pragmatic approach is needed to integrate these possibly contradicting approaches.

Overall, knowledge in the field of employment of adults with ASD is relatively young and still facing major development. Comparatively, research of employment within the general population has a rich history rooted in various disciplines. The use of well-established theories as a lens for further understanding of employment of adults with ASD is therefore warranted. Among the various theories of work, motivation has been widely researched within different disciplines (e.g., career psychology, organizational research, human resources, occupational therapy) and with relation to different contexts, including work, education, and health. Work motivation holds the potential of promoting action and perseverance. Since work can be a source of stress, with workers expected to carry out tasks in which they do not find interest or that do not match their level of training, motivation is important for maintaining long-term stability, an important goal for adults with ASD.

Common theories cluster work motivation into two basic categories: extrinsic motivation and intrinsic motivation. Extrinsic motivation to work is aimed at receiving benefits apart from the work itself, such as income or praise (Gagné

and Deci 2005). Studies show that it was found to be associated with less favorable outcomes such as lower job satisfaction, higher emotional exhaustion, impatience, lower ability to solve problems, less creativity, and more turnover intention.

Intrinsic motivation is defined as an engagement in work primarily for its own sake, because the work itself is interesting. Unlike extrinsic motivation, studies suggest that being intrinsically motivated to work has beneficial effects such as a higher sense of autonomy and higher levels of work performance and adaptation. Therefore, an intrinsic interest, achieved through matching between personal interests and environment, is one of the core theoretical foundations in vocational theories (Blustein 2013). In relation to ASD, it has been suggested that intrinsic motivation can be prompted by matching between special interests and jobs (Kirchner and Dziobek 2014; Winter-Messiers 2007).

Despite the clear benefits of intrinsic motivation, an intrinsically interesting job is not always a possibility, especially for populations faced with barriers and disabling conditions. In order to deal with this discrepancy, SDT has been suggested as a powerful lens through which work motivation can be addressed (Gagné and Deci 2005). The theory is distinct from other theories of motivation by two main conceptualizations: (a) it goes beyond the extrinsic vs. intrinsic motivation dichotomy and defines different categories of extrinsic motivation and (b) the theory addresses personal needs that have the potential of facilitating more adaptive forms of extrinsic motivation, thus “fueling” the motivational process.

With regard to the first distinction, SDT places different levels of motivation on a continuum. At one end is intrinsic motivation, considered to present the highest level of self-determined behavior, and at the other end is amotivation, which reflects no intention to act. In between, different levels of extrinsic motivation are described: On the lower end, external motivation describes an action aiming for an external desired outcome (such as earning money or getting approval), or avoiding a negative one (such as being fired); interjected motivation describes a form of motivation in

which the individual accepts the action as his own, relating to concepts such as ego involvement and self-worth (such as feeling proud or avoiding shame). This kind of motivation is considered internalized, but is still relatively controlled because it involves pressure to behave in a certain way; identified motivation accompanies actions that are congruent with personal goals and identities. Even when these activities are not intrinsically interesting or even unpleasant, they are viewed as important and hold personal significance. The higher the motivation is on the continuum, the more it involves acting with a sense of desire and having an experience of choice and self-determination (Gagné and Deci 2005).

Another aspect distinguishing SDT from other motivation theories is the conception that self-determined behavior can be achieved only when three psychological needs are satisfied: competence, relatedness, and autonomy (Gagné and Deci 2005). The feeling of autonomy provides a sense of authenticity, choice, volition, and self-regulation; Social relatedness is the feeling of being connected to others in a meaningful way; finally, the need for competence is related to a person's basic strive to experience success and a feeling of mastery. Accordingly, SDT suggests that frustration of these three basic needs can lead to a decrease in motivation.

Coming back to what we know about ASD and employment, inferences can be suggested on the basis of current knowledge: The need for *autonomy* may also involve dealing with uncertainty, which may be a source of stress for individuals with ASD. However, autonomy was identified as one of the factors leading to job satisfaction in adults with ASD (Pfeiffer et al. 2018). Furthermore, in the general population, studies did show that the need for autonomy can also be fulfilled in a structured environment (Jang et al. 2010), i.e., that autonomy is not necessarily tied with ambiguity.

Work provides an important opportunity for social interaction in daily life and a chance to experience *social relatedness*. This opportunity is especially important for adults with ASD, for whom work is sometimes the only setting for meeting other people. In contrast to the

common stereotype that individuals with ASD prefer to be alone, there is clear evidence to support their need for social engagement (Jaswal and Akhtar 2019). In the work arena, individuals with ASD mention social inclusion as a major factor leading to employment satisfaction and success (Krieger et al. 2012; Pfeiffer et al. 2018). Hence, the contribution of social relatedness experience to work satisfaction can help maintain motivation over time, without having to depend on an ongoing interest in the tasks performed.

Turning to the need for *competence*, it has been found that workers with ASD, as well as other populations, want to see themselves as good workers and take pride in their skills (Müller et al. 2003). Lorenz and Heinitz (2014) found a positive relationship between occupational self-efficacy and proactiveness, which can be considered a form of self-determined behavior.

To conclude, the basic needs portrayed by SDT hold relevance for individuals with ASD seeking stability and satisfaction in the workplace. The unsatisfactory occupational outcomes mentioned above, along with common gaps between the intellectual potential and employment demands, may detain success. To address this gap, motivational anchors like autonomy, relatedness, and competence can promote satisfaction and stability.

Future Directions

Employment of adults with ASD is a relatively new field of research, which requires more input. As current knowledge is limited in scope and depth, new research directions have the potential to spark fresh insights regarding employment of adults with ASD. Theories of motivation such as SDT can uncover the underlying mechanisms that enhance work motivation and promote other desirable employment outcomes. The emphasis on the work environment, which can be shaped and adjusted in order to respond to the workers' needs and support them, contributes to the promising notion that motivation is not just a given state, but can rather be facilitated toward a feeling of autonomy and volition. Future studies that

substantiate empirical validation of the theory in relation to adults with ASD can take us a step further in achieving this goal.

The theoretical perspective of SDT can also inform vocational practice. When facing a career choice, STD can help prioritize different considerations that should be taken into account: manifestation of interest areas, probability of success, characteristics of the social environment, work stress, and environmental factors. When an intrinsically motivating job is not available at a given point in time, other motives to work might be established. Interventions aimed at promoting employment integration can potentially prompt work motivation by focusing on fulfilling the needs for autonomy, relatedness, and competence, (Silva et al. 2014). For example, autonomy support can be enhanced by providing the option to choose between job alternatives; support for competence can be achieved by choosing gradual and realistic employment goals and offer practical guidance and support in achieving them; support for relatedness can be facilitated by enhancing relationships in the workplace, leading to a feeling of belonging. Satisfaction of these needs can be monitored by the employer or by a vocational coach through an open channel of communication. With this approach, motivational setbacks can be addressed, and needs can be answered to maintain stability and prevent attrition.

Future studies examining motivation and other work-related theories should also aim to understand workers with ASD in comparison to fellow neurotypical workers. If we aspire to create a work environment that is beneficial for all workers, motivations and needs of diverse populations should be assessed, considering their similarities and differences. Taking into account the high heterogeneity in ASD, these understandings can promote interventions that are more sensitive to individual differences and lead to a better understanding of "what works for whom". Future studies that address the issues raised in this chapter, and apply more fundamental theories of work to adults with ASD, can advance the field and pave new roads for employment success.

Definition

An employment specialist is a vocational rehabilitation professional, who assists individuals with the most severe disabilities with gaining and maintaining employment in the community by providing supported employment services. The employment specialist who may also be known as a job coach or employment consultant provides individualized services to an individual with a severe disability with all phases of the employment process which include (a) preemployment, (b) employment, and (c) postemployment. Although the type of support service provided is individualized typically the employment specialist is engaged in the following activities.

During phase one, the employment specialist conducts preemployment activities. This requires spending time setting up and implementing a variety of functional assessment activities. These

practical experiences offer both the job seeker and employment specialist with opportunities to learn more about his or her (the job seeker's) abilities, interests, work preferences, and potential on the job support needs. Then with a vision of the jobseeker in mind, the employment specialist spends time meeting with potential employers to learn more about their business needs and positions him or herself as someone who has services to meet a range of business needs including the referral of potential employees with disabilities. During this time, the employment specialist explores ways a particular job seeker may be able to make a contribution to the workplace. An informational interview and workplace analysis take place to provide the employment specialist with insight into whether or not the job seeker may be able to fill an existing position or possible ways to restructure or create a job for the job seeker. At this time, there is also a review of what type, level, and intensity of both on and off the job supports the job seeker may require if hired. If an employer seems willing to move forward with a proposition on hiring the person, then the possibilities for employment are discussed further with the job seeker and or his or her family. In particular, the pros and cons associated with the potential job offer are reviewed. If the job seeker is interested in exploring it, then an introductory meeting is arranged which depending on the circumstances may be an introductory meeting and/or a job interview.

Once hired, or during the employment phase, the employment specialist provides and facilitates a variety of on or off the job supports specifically designed to assist the new hire with learning how to do the job to meet the employer's expectations, including nonwork-related tasks such as following procedures (i.e., upon arrival and departure, taking breaks, requesting time off, etc.) and working with others (i.e., getting to know coworkers, asking for help if needed, etc.) This support often involves providing the new hire with intensive on the job site skills training (including positive behavior support) that commences after both the new hire and employment specialist participate in

the employer's new employee orientation and training program. At this time, the employment specialist may also help the new hire complete his or her job responsibilities. This work completion guarantee is designed to keep an employer satisfied while the new hire is learning how to do the job. The employment specialist collects data to evaluate what the new hire has learned and the effectiveness of the training as well as design a schedule to fade his or her presence away from the job site. Overtime, as the new hire learns the job and job-related tasks the employment specialist is there less and less time. Eventually, the job seeker is working all or most of the time on his or her own. The employment specialist remains in touch with the new hire and employer and if indicated offers additional on the job skills training or support to the worker. In a holistic approach to implementing supported employment, the employment specialist is involved in all three phases of employment. In a partitioned approach, different employment specialists may only provide a support during a specific phase or phases of employment. Among other traits, an employment specialist should possess a 4-year degree in business, education, or related area and a valid driver's license and have excellent communication skills and the ability to independently solve problems.

Definition

In general terms, employment refers to the condition of being paid for work. It can also refer to someone's trade or profession. According to the US Department of Labor employment by definition is a little more complex. The US DoL collects *Current Employment Statistics (CES)*:

CES employment is an estimate of the number of nonfarm, payroll jobs in the U.S. economy. Employment is the total number of persons on establishment payrolls employed full- or part-time who received pay (whether they worked or not) for any part of the pay period that includes the 12th day of the month. Temporary and intermittent employees are included, as are any employees who are on paid sick leave, on paid holiday, or who work during only part of the specified pay period. A striking employee who only works a small portion of the survey period, and is paid, would be included as employed under the CES definitions. Persons on the payroll of more than one establishment are counted in each establishment. Data exclude proprietors, self-employed, unpaid family or volunteer workers, farm workers, and household workers. Persons on layoff the entire pay period, on leave without pay, on strike for the entire period, or who have a pending job but have not yet reported for work are not counted as employed. Government employment covers only civilian employees; it excludes uniformed members of the armed services. (For more information about CES employment, see the CES Technical Notes at www.bls.gov/web/empst/cestn.htm#section3a. (U.S. DoL 2017a))

The US Department of Labor Bureau of Labor Statistics (BLS) conducts the *Current Population*

Survey (CPS). Here they define who is counted as employed:

People are considered employed if they did any work at all for pay or profit during the survey reference week. This includes all part-time and temporary work, as well as regular full-time, year-round employment. Individuals also are counted as employed if they have a job at which they did not work during the survey week, whether they were paid or not, because they were:

- On vacation
- Ill
- Experiencing childcare problems
- On maternity or paternity leave
- Taking care of some other family or personal obligation
- Involved in a labor dispute
- Prevented from working by bad weather

These people are counted among the employed and tabulated separately as *with a job but not at work*, because they have a specific job to which they will return (U.S. DoL BLS 2015).

If these are the governmental definitions of employment, then what is a trend? A trend is a general direction toward which a phenomenon is moving. It may be thought of as a tendency, inclination, or drift (Merriam Webster 2017). Employment trends therefore are the general direction towards which the labor market is moving. Employment trend growth refers to "...the monthly rate of payroll job gains required to hold the unemployment rate constant at a level that is broadly consistent with the Federal Reserve's maximum employment mandate, also known as the natural rate of unemployment" (Bidder et al. 2016).

Unemployment by contrast is defined as the number of people looking for paid work that are unable to obtain a paid job. Who and how people are counted as unemployed by the federal government is important. According to the US DoL BLS:

People are classified as unemployed if they do not have a job, have actively looked for, work in the prior 4 weeks, and are currently available for work. Actively looking for work may consist of any of the following activities:

- Contacting:
 - An employer directly or having a job interview
 - A public or private employment agency

- Friends or relatives
- A school or university employment center
- Submitting resumes or filling out applications
- Placing or answering job advertisements
- Checking union or professional registers
- Some other means of active job search

Passive methods of job search do not have the potential to connect job seekers with potential employers and therefore do not qualify as active job search methods. Examples of passive methods include attending a job training program or course, or merely reading about job openings that are posted in newspapers or on the Internet. (U.S. Department of Labor Bureau of Labor Statistics 2015b)

Why are these definitions important? They are important to people on the autism spectrum because they help mask or underreport the issue of employment for people on the autism spectrum. No entity, not even the federal government, collects epidemiologically based survey data on individuals with autism. At best, the federal government collects data on individuals with disabilities through its *Current Population Survey*. This lumps together a wide assortment of disabilities varying in nature from physical disability to cognitive, intellectual, developmental, or mental illness disabilities. No recognition is given to the wide variability in the employability of individuals with a variety of conditions. Furthermore, it does not include individuals who are institutionalized, incarcerated, self-employed, or who have simply given up looking for work. Countless individuals on the autism spectrum live in congregate care situations and are not counted among individuals in the labor market. Another unknown number are the number of individuals on the autism spectrum who populate our jails and prisons in the United States. They too are not counted among the unemployed. According to the most recent government estimates:

Persons who are neither employed nor unemployed are not in the labor force. A larger proportion of persons with a disability – about 8 in 10 – were not in the labor force in 2016, compared with about 3 in 10 of those with no disability. (U.S. Department of Labor Bureau of Labor Statistics 2017a)

Not including self-employed individuals among labor trends underreports the number of individuals who are working for pay. Individuals with

disabilities are more likely than their nondisabled peers to be employed. In fact, people with disabilities are more likely to be self-employed than their nondisabled peers (10.6% vs. 6.2%) (U.S. Department of Labor Bureau of Labor Statistics 2015a). In 2015, 15 million people were self-employed which made up 10.1% of all US workers. However, self-employment has trended downward in the past two decades. This downward trend is attributed to less individuals working as self-employed in the agricultural sector of the economy (U.S. Department of Labor Bureau of Labor Statistics 2015b).

Historical Background

The history of Federal legislation in reference to employment extends as far back as the Smith Hughes Act of 1917 which provided matching monies for vocational educational programs. In 1918 World War I was the impetus for the Soldier's Rehabilitation Act which sought to train disabled veterans for employment and created programs to assist veterans only (History and Regulations –IN.gov 2017). No thought was given or monies provided to individuals who were either born disabled or became disabled through any other means.

It is only a relatively recent development that we have begun to include children with autism in our education system. This system is a training ground used by society to prepare young people to be the future workers in our economy. With the passage of the Education for All Handicapped Children Act (P.L. 94-142) in 1974, the federal government established that education was a right for all children. It also established core concepts such as the right of a child with a handicap to participate in a Free and Appropriate Public Education (FAPE) in the Least Restrictive Environment (LRE). Subsequent reauthorizations of P.L. 94-142 shifted the focus to person's first language with the passage of the Individuals with Disabilities Education Act (IDEA) and created concepts such as transition goals and plans with an emphasis upon employment for all children with disabilities. According to Carter et al.

(2012) “high quality transition services and supports have evolved over the last 25 years and that finding meaningful work after high school or college has become an essential outcome of education in the United States” (p. 50). In fact:

...the Individuals With [sic] Disabilities Education Improvement Act (IDEA) of 2004, which states that a central purpose of special education is to ‘prepare [students with disabilities] for further education, employment, and independent living’ as part of a national policy aimed at ‘ensuring equality of opportunity, full participation, independent living, and economic self-sufficiency for individuals with disabilities’ (Public Law 108-442). (Carter et al. 2012, p. 50)

In the 1970s Congress also passed the Rehabilitation Act of 1973 which amended the Vocational Rehabilitation Act of 1965. The Vocational Rehabilitation Act of 1965 provided extended evaluations to determine if “more severely handicapped individuals might benefit from vocational rehabilitation services.” The Rehabilitation Act was enacted to address the issue of discrimination in the workplace against people with disabilities across the board. The most salient aspect of this act was the creation of Title V which was a major piece of civil rights legislation for people with disabilities. Under Title V four sections were created that dealt with various aspects of disability and discrimination. Section 501 required nondiscrimination in hiring of handicapped individuals in federal government and required affirmative action plans for the hiring, placement, and promotion of such individuals. Section 502 has probably the most significant impact upon our physical environment by establishing the Architectural Barriers and Compliance Board. Section 503 prohibited discrimination against handicapped individuals in employment of federal contractor or subcontractors receiving \$2,500 or more in federal monies. This section also required affirmative action plans. Section 504 prohibits discrimination against handicapped persons in ANY federally supported or sponsored program which extended the laws reach to hospitals, schools, colleges, universities, and state welfare offices or any other organization that received federal funds (History and Regulations –IN.gov 2017).

The Higher Education Opportunity Act of 2008 (HEOA) changed the rules governing Title IV or the Federal Student Aid programs. Acknowledging the importance of post-secondary education and training in the acquisition of jobs, this act helped to create Comprehensive Transition and Post-secondary (CTP) programs at colleges and universities which already have approved Title IV programs. Students with Intellectual Disabilities (ID) and other significant cognitive impairments, including those on the autism spectrum, can now access Federal Student Aid by completing the Free Application for Federal Student Aid (FAFSA). The law, as currently written, only allows students with ID to receive grants if they are enrolled in an approved CTP (FinAid 2016; Finkel et al. 2010; VanBergeijk and Cavanagh 2012).

The Workforce Innovation Opportunity Act (WIOA) of 2012 amended several employment-related laws. Most notably this law directed state offices of vocational and rehabilitative services to allocate 15% of their budgets to transition aged youth who were at risk. This included youth with disabilities and extends the notion of youth and service provision beyond the age of 21, as is the case under IDEA, to age 24 under WIOA. Under this Act VR offices can fund programs that provide pre-employment skills that were previously not funded. Individuals with autism often desperately need pre-employment skills training in soft skills such as interviewing, how to dress appropriately for work, financial literacy, how to talk to supervisors, timeliness, travel training, etc. WIOA also emphasizes employment in integrated competitive employment settings and discourages employment in sheltered workshops for sub-minimum wage.

Current Knowledge

As of October 2017, the national unemployment rate for all Americans hovered around 4.2%. This is in stark contrast to the most recent employment data for individuals with disabilities. In 2016 the unemployment rate for individuals with disabilities across the board was 10.5% or more than

double the employment rate of the nondisabled (US Department of Labor, Bureau of Labor Statistics 2017b). The contrast becomes more apparent when one looks at the employment rates between these two groups. Only 17.9% of individuals with disabilities were employed as compared to 65.3% of nondisabled individuals. Individuals with disabilities are employed at a rate that is almost four times less than nondisabled persons. The jobless rate for individuals with disabilities was consistently higher than persons with no disability regardless of their educational attainment. In fact, according to the CPS:

Persons with a disability are less likely to have completed a bachelor's degree or higher than those with no disability. Among both groups, those who had attained higher levels of education were more likely to be employed than those with less education. Across all levels of education in 2016, persons with a disability were much less likely to be employed than were their counterparts with no disability. (U.S. Department of Labor Bureau of Labor Statistics 2017b)

Not only are individuals with disabilities more likely to be unemployed, they are also more likely to be underemployed. Individuals with disabilities are more likely to be employed part-time than their nondisabled peers. This precludes these individuals from making a living wage and from receiving full-time benefits such as health insurance and paid vacation. "Among workers with a disability, 34 percent usually worked part time in 2016, compared with 18 percent of those without a disability. The proportion of workers who were employed part time for economic reasons continued to be slightly higher among those with a disability than among those without a disability (6 percent versus 4 percent). These individuals were working part time because their hours had been cut back or because they were not able to find a full-time job" (U.S. Department of Labor Bureau of Labor Statistics 2017b).

The service sector of the economy is the most likely place an individual with a disability will find employment. In 2016, 21.3% of employed individuals with disabilities worked in the service sector compared to 17.6% of nondisabled persons. "Workers with a disability were more likely than those with no disability to work in production,

transportation, and material moving occupations (14.6%, compared with 11.6%). Persons with a disability were less likely to work in management, professional, and related occupations than those without a disability (31.7%, compared with 39.5%) (U.S. Department of Labor Bureau of Labor Statistics 2017b).

The one area in the economy where individuals with disabilities and nondisabled individuals were not statistically different was in reference to government employment. People with disabilities were employed in the same proportion than nondisabled employees (14.0% vs. 13.6%). “However, a smaller share of workers with a disability were employed as private wage and salary workers (75.4%), compared with those with no disability (80.1%), and a larger share were self-employed than were those with no disability (10.6% vs. 6.2%)” (U.S. Department of Labor Bureau of Labor Statistics 2017b).

In terms of autism-specific employment trends, Shattuck et al. 2012 found in their sample, “For youth with an ASD, 34.7% had attended college and 55.1% had held paid employment during the first 6 years after high school. More than 50% of youth who had left high school in the past 2 years had no participation in employment or education. Youth with an ASD had the lowest rates of participation in employment and the highest rates of no participation compared with youth in other disability categories.”

According to data analyzed from Wave 5 of the National Longitudinal Transition Study-2 (NLTS2) by Roux et al. (2013), “. . . Approximately one-half (53.4%) of young adults with an ASD had ever worked for pay outside the home since leaving high school, the lowest rate among disability groups. Young adults with an ASD earned an average of \$8.10 per h, significantly lower than average wages for young adults in the comparison groups, and held jobs that clustered within fewer occupational types. Odds of ever having had a paid job were higher for those who were older, from higher-income households, and with better conversational abilities or functional skills. . . Findings of worse employment outcomes for young adults with an ASD suggest that this population is experiencing particular difficulty

in successfully transitioning into employment” (Roux et al. 2013).

Other analyses using the NTL-2 data revealed that “The proportion of young adults with autism who had a job was comparable to that for young adults with deaf-blindness or with multiple disabilities, and far below the proportion of those with blindness, learning disabilities, or traumatic brain injuries” (Standifer 2012). This finding suggests that autism is a far more debilitating and complex disability than most of what the public imagines. This impacts even the highest functioning and most seemingly able individuals on the spectrum. For example, according to Standifer’s analysis, “On average, young adults with autism with a job earned 86% as much per hour as all young adults with disabilities with a job (\$8.90/h vs. \$10.40/h)” (Standifer 2012). Further, Standifer (2012) found, “Nearly half of employed young adults with autism earned less than \$7.25 an hour, twice the rate for all employed young adults with disabilities (44% vs. 22%).” His analysis also concluded that, “Nearly half of employed young adults with autism worked less than 20 hours a week, four times the rate for all employed young adults with disabilities (42% vs. 11%).” Even the “Average hours worked per week by young adults with autism was 36% lower than that for all young adults with disabilities (23.2 hrs. vs. 35.8 hrs.),” according to Standifer (2012). The final two facts of Standifer’s analysis really underscore the plight of individuals on the autism spectrum when it comes to employment: “The proportion of employed young adults with autism who were working full time (35 h or more per week) was one third that for all young adults with disabilities who had a job (26% vs. 71%),” and “The proportion of employed young adults with autism who worked in a sheltered workshop environment (only working with other people with disabilities) was seven times that for all employed young adults with disabilities (34% vs. 5%)” (2012). This makes it far more difficult for an individual on the spectrum to earn a living wage in order to be able to support themselves. This comparison, again, is in relation to peers with other types of disabilities and not nondisabled peers.

No blanket statement or trend can be made in reference to employment of individuals with an ASD. The manifestation of ASD is unique and individual. Consequently, each person on the spectrum needs to carefully consider his or her unique strengths, interests, and deficits. A key factor will be to realistically ascertain the level of education and or training the individual can successfully complete. After exploring each of these domains, individuals on the spectrum and their family members should explore the US Department of Labor Bureau of Labor Statistics publication known as the *Occupational Outlook Handbook*. This publication is updated on a quarterly basis and has the most up to date labor projections for the next 10 years. One feature of the *Handbook* that is particularly helpful is the Occupation Finder. This feature has an A–Z listing of the 818 federally recognized occupational titles. Readers can scroll down through the document to find a job title of interest or something close to their vocational interest by clicking on the job title itself; it will link the reader to similar job titles. In addition to the occupational titles, readers will learn the entry level educational requirements for the position, any on-the-job training requirements, projected number of new jobs, projected growth rate, and the previous year’s median pay.

In reviewing the *Occupational Outlook Handbook* some general statements can be made about employment trends over the next 10 years. The service industry is where the majority of jobs can be found. Specifically, the healthcare/eldercare will have the greatest amount of growth and the largest number of actual job openings. Working in some of these positions can be especially challenging for individuals on the autism spectrum because this directly abuts their difficulties in social communication, and dealing with variable working conditions. From Table 1, we can see that there are a variety of occupations that are in the health-care field and require various levels of education or training. Under the occupational title system, generally any position in the health-care field that has the word aide attached to it requires the lowest level of education or training. Frequently, this is a vocational certificate and/or

Employment Trends for People with ASD,
Table 1 Twenty fastest growing occupations with greatest growth rate 2014–2024

Occupation	Growth rate 2014–2024 (%)	2016 median pay (per year)
Wind turbine service technicians	108	\$52,260
Occupational therapy assistants	43	\$59,010
Physical therapist assistants	41	\$56,610
Physical therapist aides	39	\$25,680
Home health aides	38	\$22,600
Commercial divers	37	\$49,090
Nurse practitioners	35	\$100,910
Physical therapists	34	\$85,400
Statisticians	34	\$80,500
Ambulance drivers and attendants, except emergency medical technicians	33	\$23,850
Occupational therapy aides	31	\$28,330
Physician assistants	30	\$101,480
Operations research analysts	30	\$79,200
Personal financial advisors	30	\$90,530
Cartographers and photogrammetrists	29	\$62,750
Genetic counselors	29	\$74,120
Interpreters and translators	29	\$46,120
Audiologists	29	\$75,980
Hearing aid specialists	27	\$50,250

completion of high school. Those positions in the health-care field, such as occupational or physical therapy assistants, require an associate degree level of education. Outside of the health-care field, cartographers and photogrammetrists are occupations that will have a 29% growth rate in the coming decade with a 2016 median annual

salary of \$62,750. This position, however, requires a bachelor degree level of training. For those individuals on the autism spectrum who are visually oriented and have a talent for pattern recognition, this occupation may be a suitable profession that pays a living wage. Some individuals on the spectrum have been employed by intelligence and military agencies in helping interpret satellite image data. For those individuals on the spectrum who are more quantitatively oriented and can complete either a bachelor's, master's or even Ph.D. level of education, operations research analysts' positions may provide meaningful and lucrative employment. Persons in this position use mathematical and analytical models and methods to help organizations identify and solve complex problems facing the organization in which they work.

What we know is that individuals on the autism spectrum who leave high school are more likely to be employed when several factors were taken into consideration beyond personal demographics. Graduating from high school, whether the student ever received career counseling in high school and whether the high school contacted postsecondary vocational training programs or potential employers are significant factors in participating in employment with this population (Chiang et al. 2013). Ohl et al. (2017) in their study of 254 adults with ASDs, found that participants who disclosed their ASD diagnosis were three times more to be employed when compared to individuals who did not disclose their diagnosis. They also found that education level was a significant predictor of employment status with higher levels of education being associated with employment. Pillay and Brownlow (2017) conducted a systematic literature review of 297 articles concerning postsecondary employment of young adults with ASDs. Of the 297, articles only eight studies met their full inclusion criteria. Pillay and Brownlow (2017) established four predictors of employment, namely – supported workplace intervention, ASD traits and behavioral intervention, functional independence intervention, and family advocacy intervention. The odds of gaining employment were greater for youth who received job placement services from their local

Vocational Rehabilitation Program; however, only 48% of youth with ASDs received such services according to Migliore et al. (2012). This group of researchers also found that postsecondary college services were the strongest predictors of better earnings, and yet, only 10% of their Vocational Rehabilitative Services data set received college-based services. Although not focused solely on autism per se, Carter et al. (Carter et al. 2012) found that: "Having held a paid, community-based job while still in high school was strongly correlated with post-school employment success. In addition, being male and having more independence in self-care, higher social skills, more household responsibilities during adolescence, and higher parent expectations related to future work were all associated with increased odds of employment after school for young adults with severe disabilities" (p. 50). A long-standing finding from Wehman (2001) contends that for students with disabilities even completing one college course significantly increases the odds that they will be employed. Furthermore, those students with a disability, broadly defined, who are able to complete a bachelor's degree are hired at virtually the same rate as their nondisabled peers. More recently, Wehman et al. (2013) conducted the first randomized clinical trial of vocational training as an intervention for transition aged youth on the autism spectrum. The control group was "business as usual condition" which meant that the students worked with their local school district and vocational rehabilitation office in an effort to find employment. Transition aged youth randomly assigned to the business as usual condition were employed at a rate of 6%. By contrast transition aged youth who received vocational training were employed at an 87.5% rate. These jobs were in a hospital setting and provided a living wage. The results suggest that for youth on the spectrum who are unable or not interested in pursuing a college degree, postsecondary employment training is an effective intervention in helping them gain employment. Moore and Schelling (2015) examining National Longitudinal Transition-2 study data found that students with intellectual disabilities, which included some students on the autism

spectrum, who attended postsecondary education programs, had positive employment outcomes when compared to individuals who did not attend such programs.

Future Directions

In order to fully understand the light of individuals on the autism spectrum, we need to collect epidemiologically based data in reference to employment. The Federal government by asking generic questions concerning disability is unable to determine how many individuals with ASDs are employed, underemployed, unemployed, or not even in the labor force. Small samples of nonrandomly selected participants in research studies give us a wide range of unemployment rates that may not represent the larger population.

A second area of study is one that examines the impact of Federal legislation upon the employment rates of people with ASDs. Namely, we need to examine how IDEA and the Individuals with Disabilities Education Improvement Act of 2004 (IDEIA), with its emphasis upon empirically based intervention techniques, transition goals, transition plans, and employment outcomes, have possibly improved the employment picture for the ASD population. Likewise, how has the Higher Education Opportunity Act of 2008 and the creation of Comprehensive Transition and Postsecondary (CTP) programs, (which provided access to Federal Financial Student Aid in the form of grants), affected the employment outlook for individuals on the spectrum and how this has affected the financial health of their families? The Workforce Innovation Opportunity Act (WIOA) of 2012 is the final piece of federal legislation we must evaluate in terms of its impact upon the employability of individuals on the spectrum.

A third area of study involves the efficacy of various postsecondary college-based or college affiliated transition program models. This future research must examine which program components are most effective in helping transition aged youth find and obtain gainful employment.

The research must examine not only academic course content and employment training but also assistance with social skills and social communication as well as independent living skills such as financial literacy skills, travel training, cooking, self-care, apartment management, and laundry.

A final area of future study should examine how professionals can capitalize upon the distinct but varied learning styles of individuals with ASDs. Grandin and Duffy (2004) identified these styles as “visual thinking (or thinking in pictures), music or higher math brain types, and verbal lists and language translator brains.” The challenge will be how professionals can first identify these learning styles and then match those styles to existing jobs in our economy in both the present and in the future.

Enactive Mind

Fred R. Volkmar

Child Study Center, Irving B. Harris Professor of Child Psychiatry, Pediatrics and Psychology, Yale Child Study Center, School of Medicine, Yale University, New Haven, CT, USA

Synonyms

Enactive mind hypothesis

Definition

This theoretical model for understanding social difficulties in autism was inspired by the major gap typically observed in performance of

cognitively able individuals with ASD in their ability to correctly respond to explicit tasks of social reasoning and their typical major inability to perform in naturalistic social situations (Bowler 1992; Dahlgren and Trillingsgaard 1996). This inability is reflected pervasively in daily life and is a source of major disability (Klin et al. 2000). It is reflected in standard measures of social competence, e.g., in adaptive behavior as assessed by the Vineland (Volkmar et al. 1987).

This discrepancy has significant impact on activities of work and daily living. One solution for such individuals is often an overreliance on routine and structure avoiding novelty and, as much as possible, the inherent unpredictability of social life. This solution often leads to significant social isolation and loneliness for even the most cognitively able persons inspired by a series of studies focusing on naturalistic social situations (e.g., Klin et al. 2003). Klin and colleagues proposed that the discrepancy in performance between naturalistic and highly structured situations may be even greater than what was originally believed. Their work with eye tracking revealed major and profound differences in observation of social situations with critical elements of social scenes frequently missed entirely. The inability to encompass the quickly changing social panorama and rapidly select the most salient features of a scene before responding was dramatic and illustrated the need for new conceptualizations of these difficulties.

In their model Klin and colleagues (2003) provided an alternative to computational models of social-cognitive development. The enactive mind (EM) approach was based on emerging embodied cognitive neuroscience. In the EM model, cognition is seen as embedded in experience that results from the body's action on the relevant and salient aspects of the environment. Thus, social cognition is viewed as embedded in social interaction. These experiences become tools for social adaptation that can also be abstracted symbolically and used for explicit reassigning about social phenomena.

In autism, the EM approach suggests that these preceding processes are derailed given that the typical primary salience of social stimuli

is not present and is replaced, de facto, by an overreliance on the physical world. This pattern thus shapes phenomena like joint attention, incidental learning, social communication, and so forth. Put another way it leads young children with autism to become experts on things rather than on people. Thus, even for the most cognitively able individual the lack of reliance on embedded personal experience resulting in major difficulties in ever-changing naturalistic social situations. The EM approach contends that without the set of embodied social-cognitive tools interaction in such situations becomes halting, slow, and inefficient.

This approach emphasizes that individuals with ASD can learn about people but in a way that is not the normative model of social learning. As a result, their knowledge can be highly sophisticated in many respects in the abstract but highly limited in realistic interactions. This approach suggests the importance of studying compensatory pathways and approaches that move beyond highly structured laboratory situations into more naturalistic ones.

Encopresis

Irma Isasa
Child and Adolescent Service, Polyclinic
Gipuzkoa, San Sebastián, Spain

Synonyms

[Fecal incontinence](#); [Soiling](#)

Short Description or Definition

Encopresis, as defined by the DSM-IV-TR (American Psychiatric Association [APA] 2000), consists in the repeated passage of feces in inappropriate places. Although soiling is usually involuntary, it may be intentional in some cases. Soiling must occur once a month for at least 3 months and the chronological age of the child must be at least 4 years. In the case of children with developmental delays, a mental age of at least 4 years is required in order to characterize for a diagnosis of encopresis. Any physical disorder, explaining incontinence, must be ruled out and the soiling should not be due to the direct effects of a substance (e.g., laxatives).

Categorization

Encopresis can be categorized as primary or secondary. In the case of primary encopresis, the fecal continence has never been obtained; and in secondary encopresis, there has been a period of fecal continence (defined as having reached continence for at least a period of 12 months) preceding the recurrence of soiling.

The DSM-IV-TR describes two subtypes of encopresis:

- Encopresis with constipation and overflow incontinence, which has been referred in the literature as “retentive encopresis.” On physical examination there is evidence of large stool mass on abdominal or rectal examination and a history of stool frequency of less than three per week. Usually, there are periods of retention which last several days, followed by a painful expulsion, and then the period of retention starts again.
- Encopresis without constipation and overflow incontinence, which has been referred in the literature as “non-retentive encopresis.” Here, there is no evidence of constipation on physical examination or by history, and the feces are likely to be of normal consistency. Here the main characteristic is the lack of psychological, physiologic, or combined control of the expulsion.

Epidemiology

It is estimated that 1% of 5-year-old children have encopresis, and the disorder is more frequent in males (APA 2000).

There are different studies involving children of different ages, with a prevalence varying between 1.5% and 4.1% and a male-female ratio of 3:1. The prevalence of encopresis is higher among younger children (Bellman 1996; Mikkelsen 2007; Van Der Wall et al. 2005).

Special Characteristics of Encopresis in Children with Autism

The figures reported before pertain to the general population. In children with autism, there are just a few studies to review. Data collected from these studies suggest that constipation in this population has a behavioral etiology, rather than a primary organic gastrointestinal etiology. The overall incidence of gastrointestinal symptoms among children with autism did not differ from children without the disorder (Ibrahim et al. 2009). Children with autism have an increased incidence of difficulties, regarding not only constipation but also feeding behavior and food selectivity, which are understood as related to behavioral problems, rather than to organic gastrointestinal pathology (Ibrahim et al. 2009).

Natural History, Prognostic Factors, and Outcomes

There have been several studies (Mikkelsen 2007; Loening-Baucke 1987; Loening-Baucke et al. 1987) to find out the basis for the encopresis. It seems clear that retentive encopresis has a direct relationship with abnormal contractions and an inability to relax the external sphincter. Even more, this problem very often generates a constipation problem, with painful defecation, which leads again to retention, making the problem bigger and bigger. The consistency of the stool becomes harder, making the process more painful and difficult. And the child avoids defecation, until leakage occurs.

In the non-retentive encopresis, psychological issues such as oppositional defiant or conduct disorder can be identified. Also, in the case of developmental disabilities, one can suspect that proper toileting behavior has never been mastered.

Clinical Expression and Pathophysiology

Constipation and functional fecal retention (FFR) have been included as causes leading to the development of retentive encopresis. It should include a period of a minimum of 12 weeks of constipation history, large stools, abdominal pain, soiling, and the need to use laxatives or enemas to treat the problem.

It seems clear that constipation and painful defecation are associated with stool toileting refusal (STR), and in most cases, hard and/or painful bowel movements occur before the onset of STR. Therefore, an effective treatment for constipation may be an option to decrease the duration and/or the incidence of STR (Blum et al. 2004). Constipation is a frequent and significant problem that happens in children suffering from autism. It is difficult to recognize its impact and how it functionally affects the rectosigmoid colon. It is often associated with megarectum. Since there is no significant correlation between the degree of fecal impaction and the clinical history, the importance of an abdominal radiography during the assessment, to evaluate the degree of constipation, is essential (Afzal et al. 2003).

Behavioral problems may be the primary or sole symptom of the underlying medical condition (Buie et al. 2010).

Evaluation and Differential Diagnosis

Soiling can be an original problem or a symptom of a different cause. Therefore, it is important to rule out possible physical or psychological causes. In typically developed children, there may be times when soiling and/or wetting accidents can occur, and if these are repetitive, the clinician must identify possible coincidental

stresses. Usually the problem remits when the stressor is removed. Other times, there may be physical or medical causes such as Hirschsprung disease, stenosis of the rectum, endocrine abnormalities, and other medical conditions that must be ruled out. Also, for a variety of different reasons, other problems such as attention deficit hyperactive disorder (ADHD), oppositional defiant disorder (ODD), and, again, developmental disorders like mental retardation or autistic spectrum disorders (ASD) can be associated with encopresis.

Soiling in children suffering from an autistic spectrum disorder (ASD) can include all the physical and psychological causes that must be considered in typically developing children. Peculiar aspects playing a role in ASD may include:

- Rigidity that leads where and when they defecate, leading to constipation
- Refusal to seat on the toilet
- Absence of appropriate learning of the toilet use
- Diet problems, leading to constipation
- Soiling challenging behavior, such as smearing feces and playing with them
- Social cognition limitations hampering their understanding about using toilets and when and how the toilet should be used
- Sensory anomalies involving olfactory, tactile sensations, or even the noise produced by the toilet that can generate refusal among ASD children

It is important to find out what are the possible one or more involved factors and include them into a coherent treatment plan.

Treatment

Once medical problems have been ruled out, we should check for psychological/behavioral explanation of the problem and treat accordingly.

Treating Anxiety Symptoms

We should keep a very close attention to anxiety symptoms that could lead to suffering and

avoidance of toilet use. We should encourage the use of the toilet in a positive and progressive way, coupling the toilet situation with rewarding and pleasant stimuli. Since changing routines is difficult for these children, they will need more time and effort to adapt to this challenging task.

Minimizing Understanding Difficulties

When giving tips or messages regarding the use of the toilet, it is important to ensure proper understanding. Therefore, the use of augmentative communication systems, using, for example, gestures, objects, pictograms, or pictures, may be quite helpful.

Treating Physical Causes

If poor diet is the problem leading to constipation, the bowel may be blocked with hard stools, painful to pass, and that may even cause fissures in the perianal area. The child, therefore, will try to avoid passing them because it is painful and the stools will become harder and may even further challenge passage through the bowel. There is usually leaking through the passage that stains the underpants. In children suffering from ASD, the fact that their clothes get stained may not be an issue for them, due to social unawareness, but there will be negative feedback obtained from peers or non-informed adults.

Measures to resolve this problem may be increasing high-fiber foods such as bran, whole wheat products, vegetables, and fruits or even increasing the liquids in the diet adding water or juices. Also the reduction in constipating foods like bananas, dairy, and peanuts can help. Most people react with a gastrocolic reflex, by feeling the need to defecate just after having a meal; and this can be used as a simple mechanism to favor appropriate defecation.

These general dieting advices may be important when diapers are removed for the first time and training is attempted.

Treating Sensory Problems

The physical structure of the toilet is very important and involves “isolating” the place (avoiding distracters) and the behavior (sits on the toilet to defecate or urinate only). It is not easy to assign a half-bath in every house, but if possible it can be

very helpful, to avoid distractions and confusing issues. Creating a secure and not overstimulating environment is important, to make the child more relaxed and comfortable. Therefore, think of the plumbing noises, echoes, and lights. Even playing soft music can help.

Treating Rigidity Problems

Establishing a visually supported routine can be crucial. We must create a visual sequence of steps that help the child to complete the goal. Since children presenting ASD have preferences for routines or rituals, we can create new ones to make a bridge between the old and the new ones. We could start with a transition object (a photograph, a picture, or an object of the toilet) that serves to initiate the bathroom routine. Once the transition to the toilet has been made, it is important to continue with the visual aids to visually support each step of the toileting routine. Those aids can be placed in a ziplock bag or glued shut.

Treating Refusal to sit on the Toilet

When resisting to sit on the toilet is an issue, we must break the target into as many steps as needed. Sometimes these children have motor planning difficulties, and although they may know the next step, they seem unable to physically move themselves. Therefore, we should physically help them to initiate the movement. Other times we may use desensitization, a behavioral technique useful to help the child decrease the fears over different situations such as sitting on a toilet and the noise of flushing it, step by step. For example, tips like sitting on the toilet without removing the clothes, using timers, using the length of one song on the CD player, entertaining the child, taking turns sitting on the toilet, and using dolls for modeling can be helpful. The adult must recognize that it may take time for the child to extinguish his or her fears. We also should be aware that they have difficulties imitating and generalizing behaviors.

If flushing the toilet is an issue because the child is afraid of it, one can try starting the flush while the child is away from the toilet and gradually help him or her to get closer. Give warning in advance. Show him how to do it and make a

“game” of it. If the problem is the opposite, and flushing is an intense interest, use visual sequence to show the child when to flush, and what follows afterward (washing hands, lights off, leave toilet), to help him to get distracted from this interest.

Treating Social Difficulties

The use of social stories about the use of the toilet can also help. By them, children with ASD can understand when and how to use a toilet, who can support them if they need help, how to ask if they need using the toilet, and where to locate one when they are not at home.

Treating Other Difficulties

There may be other difficulties such as playing with the toilet paper or even resisting being cleaned that need to be tackled. In those cases one can try using Kleenex, wet wipes, or a sponge. At the same time, we should reinforce all the desired behaviors such as spending more time sitting on the toilet, flushing it without fear, or doing so for the appropriate length of time.

When planning a structured program for potty training in children with ASD, three basic components should be covered: *order*, *predictability*, and *routine*. Each program has to be individualized, and we should not forget that potty training is a process, not an event. It should include visual supports, social stories, and very important individualized personal potty stories.

For parents it is also important, before beginning with the plan, to write the reasons that have caused them anxiety over potty training and understand why training has not been successful in the past. It is useful for them to anticipate any obstacles that will be found and consider ways to overcome them. Also it should help to write the strategies to be followed and think about the benefits generated when potty training is achieved.

It is mandatory to keep track of the progress (and difficulties) and to share them with the clinician or educator. First, a baseline observation time recording the time or times in the day where the “accident” takes place, and then, most people find that it is useful to consider this “likely times” and proceed before they happened, using the previously mentioned tips.

The investment in this training sooner or later pays back, and this achievement helps the dignity, autonomy, health, and social status of the child with previous encopresis.

Endep

- [Elavil \(Amitriptyline\)](#)

Endep (Amitriptyline)

Ayodola A. Adigun

Yale Child Study Center, New Haven, CT, USA

Albert J. Solnit Children's Center, Middletown, CT, USA

Synonyms

[Amitriptyline hydrochloride](#)

Definition

Endep is an antidepressant. The drug works on the brain by increasing the level of neurotransmitter chemicals, norepinephrine and serotonin, and blocking acetylcholine. While there is some evidence of its effectiveness with symptoms accompanied by hyperactivity, impulsivity, aggression, and self-injury of treatment-resistant youth with ASD at low doses, further research is required. Endep can be used for bed-wetting, provided that there are no primary bladder issues. Side effects may include weight gain, dry mouth, nausea, and constipation. Clinicians must perform quarterly EKG to evaluate heart irregularities.

Endophenotypes

Paul El-Fishawy
State Laboratory, Child Study Center, Yale
University, New Haven, CT, USA

Definition

A phenotype is a characteristic of an organism or individual that can be observed. In psychiatry, the term is often used to refer to a set of behaviors that constitute a categorical diagnosis. An endophenotype is a measureable characteristic that exists somewhere along the biological pathway from gene risk to the overall phenotype or categorical diagnosis. It is a characteristic that may reflect an underlying or component feature of a disorder, such as autism. The characteristic can be of many types, including biochemical, neurophysiological, neuroanatomical, and cognitive (Viding and Blakemore 2007). It can be a subset of the clinical symptoms but not the full syndrome itself. For example, “age at first word”

has been proposed as an autism endophenotype (Alarcón et al. 2002). While it clearly relates to language disability, it is not the entire autism phenotype. Some terms have similar meanings but do not focus on the genetic connection. These include “intermediate phenotype,” “biological marker,” “subclinical trait,” and “vulnerability marker” (Gottesman and Gould 2003).

Historical Background

The term endophenotype was introduced into the psychiatric lexicon in a 1972 book on the genetics of schizophrenia by Irving Gottesman and James Shields (1972). They borrowed the term from a paper by John and Lewis who had used it to describe concepts in evolution and insect biology (Lewis 1966). Gottesman and Shields proposed the endophenotype concept in an effort to speed discovery of genes that contributed to neuropsychiatric disorders, especially Schizophrenia (Gottesman and Gould 2003).

The idea was that the complexity of neuropsychiatric behavioral phenotypes would likely result from the dysfunction of a greater number of genes than would less complex endophenotypes of these disorders (Gottesman and Gould 2003). The discovery of genes that contributed to endophenotypes, therefore, would help speed gene discovery in neuropsychiatric disorders both because the genes that contributed to endophenotypes would presumably also contribute to the disorder and because the genetic research and analysis involved in the discovery of genes resulting in an endophenotype (with fewer genes contributing) would be easier than the discovery of genes resulting in a full-blown neuropsychiatric phenotype (with multiple genes contributing).

In 2003, Gottesman and Gould published a paper updating and further elucidating the endophenotype concept in psychiatry (Gottesman and Gould 2003). They proposed the following five principles, some of which were adapted from those suggested by others, that they state make an endophenotype useful for genetic research:

1. The endophenotype is associated with illness in the population.
2. The endophenotype is heritable.
3. The endophenotype is primarily state-independent (manifests in an individual whether or not illness is active).
4. Within families, endophenotype and illness co-segregate, (meaning that those with the endophenotype have the illness and those without it do not have the illness).
5. The endophenotype found in affected family members is found in nonaffected family members at a higher rate than in the general population (Gottesman and Gould 2003).

As pointed out by Gottesman and Gould, the endophenotype concept lay dormant and largely unutilized from the time of their introduction of the concept to the psychiatric literature in the 1970s until the start of the twenty-first century (Gottesman and Gould 2003). However, in the new century, researchers began to utilize the concept significantly more frequently. Gottesman and Gould attribute this change to the lack of success of numerous genetic studies utilizing phenotypes as opposed to endophenotypes in discovering genes that contributed to neuropsychiatric disorders despite significant investments and large-scale projects (Gottesman & Gould). The slowness of the progress was certainly evident in research into the genetics of autism (El-Fishawy and State 2010). Regardless of the reason, the use of endophenotypes proliferated substantially after the year 2000 in neuropsychiatric research in general and in genetic research in autism in particular, as described below (Gottesman and Gould 2003).

Current Knowledge

The endophenotype concept has been used in multiple studies seeking to identify genes contributing to autism spectrum disorders. For example, a study by Alarcon et al. linked a region on chromosome 7 to an autism endophenotype, “age at first word” (Alarcón et al. 2002). Subsequently, this group found evidence for association of this

endophenotype to a specific gene in this interval called contactin-associated protein-like 2 (CNTNAP2). A series of subsequent studies have pointed to the involvement of CNTNAP2 in language development and autism (Abrahams and Geschwind 2010).

Multiple other endophenotypes have been explored with regard to autism genetics. For example, there has been a long-standing interest in the observation of increased platelet serotonin levels in individuals with ASD (Anderson et al. 1987) and whether this might serve as a useful endophenotype for gene discovery (Freitag 2006). Similarly, enlarged head size, or macrocephaly, has been demonstrated in a subset of autistic children (Sacco et al. 2007). In this regard, rare cases of mutations in the gene *PTEN* (*phosphatase and tensin homolog*) have been found in individuals with macrocephaly and autism. These findings have been robust enough to warrant the recommendation that individuals with these features should have a genetic evaluation including sequencing of this gene.

Quantitative scales have also been developed focusing on identifying potential endophenotypes in autism. For instance, scores on the Social Responsiveness Scale (Constantino and Todd 2005), aimed at measuring the severity of social impairment, have been shown to be heritable and continuously distributed in the population, with parents of autistic children showing significant shifts toward pathological scores (Constantino and Todd).

Future Directions

Several avenues of autism research have characterized traits that could potentially serve as novel endophenotypes. For example, eye-tracking experiments and functional neuroimaging have identified potential signatures of autism risk. Simultaneous advances in genomic technologies will increasingly allow these to be explored.

Importantly, as specific risk genes and regions have been identified based on the categorical diagnosis of ASD, it has become clear that these

genetic factors also increase the liability for a wide range of disorders that were previously conceptualized as being distinct. For example, duplications of a section on the short arm of chromosome 16, 16p11.2, have been shown to increase the risk for both autism and schizophrenia. Studies are just now being undertaken examining whether these and similar findings may, in part, reflect shared endophenotypes among disparate clinical syndromes (State and Levitt 2011).

The history of Autism is a discourse (Waltz 2013), a journey through a disputed landscape, whose territories are alternatively staked by Politics, Education, Society, and Culture. It is diachronic in nature, as the knowledge of the present is built upon the past, but a diachronic that has progressed differently in different states, at different rates as each impact upon each other. Essentially its origins are lost in myth (Frith 1992) but its presence has always been felt in one way or another, even before the concept of autism was framed in the Western psychiatric narrative.

It is important for the continued understanding of the position that autism occupies as a “phenomenon” in England to restore the emphasis of the narrative to the cultural landscape as this is the day-to-day experience of people living and working with this contested construct and category of humanity. Although the discourse of autism has been framed by professionals and academics, it is in reality only one side of the triangle, whose base is the people who have been ever increasingly subsumed into the category, while on the other side of the professionals are the parents who have applied political pressure and undertaken practical projects to improve the lives of their children. In the middle is everything else, media representation, popular fictions, and alas a cloud of misunderstanding. However, without autistic people themselves, there would be no discourse at all. It is then a landscape of neurological

difference emerging through the subjective experience, upon which political and cultural divisions have been drawn.

Early History

Although Autism as a term was not coined until 1912, or formally delineated until the 1940s, its phenotype can be found in England at the beginning of the psychiatric narrative through a new understanding of the writings of John Langdon Down (Waltz 2013). It can also be found in literature in the equally astute observations of authors whose fictional characters are based on their perspicacity. Sherlock Holmes springs instantly to mind, but there are examples to be found in Dickens, Hardy, and so on, going all the way back to Shakespeare, whose professional clown Robert Armin wrote “foole on foole” both a history of his profession and a narrative of the “natural,” among which descriptions you can be certain to find the traits of autism as it is now conceived (Mc Donagh 2008).

Current understandings of autism emerged mostly after the Second World War, with the predominant psychoanalytical school holding sway with the notion of the “refrigerator mother” precipitating her offspring into the form of the unreachable child afflicted with some kind of severe psychosis, to use Bettelheim’s metaphor of the “empty fortress.” In cultural terms, it has become an othering narrative (Said 1977) whose effect on the popular perception of the autistic can still be seen today in popular fiction. For example, Stuart Murray instances (Murray 2008) an Observer Sunday supplement article of the mid-1960s dealing with the “pioneering” efforts of the Lindens school to “reach” autistic children and prepare them for mainstream schooling.

It is important to remember that Education in England since the 1944 education act was predicated on separation of children into categories one of which was Educationally Subnormal (ESN) further subdivided into moderate and severe. Children in the severe category were deemed as “ineducable” and only capable of training. Most children who would then have been identified as

autistic (if at all) would have fallen into one of the ESN categories. This was a state of affairs that was perhaps first challenged in 1962 by a group of London-Based parents (including Lorna Wing q. v.) who decided to take matters into their own hands forming the Autistic Children's Aid Society of North London to establish a school for the education of their autistic children. The Sybil Elgar school was opened in 1965 and the Helen Allison school in 1968. As with many societies who had been established in a similar fashion by parents of children with a range of impairments, there were some with purely local and others with a regional or national scope.

In time the North London group assumed a national focus, and with the realization that autistic children grew up to be autistic adults, dropped the "children" from the title becoming what we now know as the National Autistic Society (NAS). This was a pattern reflected by other impairment groups who had focused originally on children.

Research

One of the earliest researchers to take an interest in the phenomenon of Autism was Sir Michael Rutter who has been associated with the Institute of Psychiatry Kings College London since 1965, firstly as a consultant psychiatrist at the Maudsley hospital and later as the first chair of child psychiatry. He currently holds the position of professor of Developmental Psychopathology. Although Rutter can best be characterized as "old school" in terms of current developments in the study of autism (particularly in terms of gender qv), he did contribute much to the field of epidemiology and helped to establish autism as a probably genetic condition in reaction to the former psychoanalytical and behaviorist perspectives, thus helping to put the study of autism on a firm scientific footing.

The 1970s saw changes in education, leading to the establishment of special schools and following on the publication of the influential Warnock Report this was crystallized into the 1981 Education act, with the widespread use of

"special needs" as a category replacing "subnormal" a broader term encompassing a range of impairments and disabilities including autism, with an emphasis on mainstream schooling with appropriate provision for those needs with the role of the Special Educational Needs Co-ordinator (SENCO) being prominent. The 1970s were also a time for the broadening of the phenotype of autism to include a larger population of autistic people hitherto unrecognized.

Lorna Wing in particular, with her NAS colleague Judy Gould, has arguably made one of the greatest contributions to the understanding of Autism through the introduction of the concept of an "autistic spectrum" (Wing and Gould 1979) to refer to this broader conception of the term "autism" which came about after one of the first widespread epidemiological surveys in Camberwell identifying a larger number of people with the traits of autism than those previously recognized as having the condition. Along with Uta Frith, Wing also helped to introduce the work of Austrian Paediatrician Hans Asperger to the English-speaking world. At the time she saw the use of the term Asperger's (or Asperger) syndrome as less stigmatizing to autistic people whose intelligence fell within and beyond the normal range.

Uta Frith, who completed her PhD in Autism in 1968 at University College London, has also been an influential writer and researcher bringing the study of autism as a neurocognitive phenomenon into greater prominence. She developed the weak central coherence explanation of autism which in common with Asperger's paper, which she was the first to translate into English, recognized strengths as well as deficits in autistic cognition. As author of "Autism Exploring the Enigma," she also strayed into cultural territory giving an overview of what Autism might have looked like in historical times. She has supervised a number of researchers who have gone on to prominence including Francesca Happé who has further developed the central coherence theory (Happé 1999), and Frith also supervised Simon Baron-Cohen (qv).

The seventies and on into the eighties also saw other developments in the perceptions of

disability which would have a subsequent impact on the landscape of Autism.

With growing social awareness and paralleling the civil rights movement of the USA and anti-apartheid movements in South Africa, segregation became to be seen by groups of radicalized disabled people as an experience not unique to race and something accomplished by the educational system, institutionalized care and prejudicial treatment of disabled people in the workforce. Out of this grew, the social model of disability which posited that disability arose from societal attitudes and barriers, and impairment was not its cause (Oliver 1990; Finkelstein 1975).

In terms of legislation, the 1970s brought in the Chronically Sick and Disabled Persons Act, which began to confer new rights to individuals (autistic people and the parents of autistic children among them) and new duties upon local authorities and health providers, and ushered in Social Services departments.

Another force for social change was the growth of an “antipsychiatry” movement which questioned the basis of contemporary psychiatry as more of a means of containment and control than directed toward recovery, drawing on the works of Foucault and Goffman and exemplified by RD Laing as a radical psychiatrist in England. Autism research would thus far seem to be untouched by this movement except so far as to become finally detached from its initial consideration as a psychosis and possible form of childhood schizophrenia through its inclusion in the Diagnostic and Statistical Manual, third edition (DSM-III) of the American Psychiatric Association in 1980 (APA 1980).

Simon Baron Cohen, based at the Autism Research Centre Cambridge University (founded in 1998), did much to popularize the “Theory of Mind” model which he had developed in 1985 (Baron-Cohen et al. 1985). He has subsequently gone on to more controversial research positing the Extreme Male Brain Theory (Baron-Cohen 2002), which has been challenged by Autistic scholars such as Melanie Yergau and others including the authors of this article (Yergau 2013).

Dinah Murray developed the interest theory of Autism (readers may be more familiar with the terms single attention and monotropism) with Mike Lesser (Murray et al. 2005). Although this has not become a mainstream model of autism to the extent of Theory of Mind or Central Coherence, it has nevertheless found favor with Autistic scholars as a fairer means of describing the neurological mechanisms of autism than any specific model which posits deficit. Murray argues that Autistic people’s strengths and special interests can play an important role in their education and provide a dividend for the employment of autistic people as adults as instanced by the work of Specialisterne, who have been elsewhere in the UK employing Autistic people in testing software.

Research Autism was established by the NAS in 2004 to evaluate and raise funds for research into interventions in Autism as well as providing authoritative guidance for professionals and the public on the bewildering variety of interventions that exist. It is currently winding down with its functions being reabsorbed into the work of the NAS.

Current Centers for Research, Education, and Publishing

While most of the research into autism has been conducted within the medical framework, there has been a significant focus on Education with certain programs attracting an increasing number of autistic students and researchers such as the Autism Centre for Educational Research at the University of Birmingham and the Sheffield Hallam University Autism Centre’s Post Graduate Certificate run in conjunction with the NAS, both of which have included autistic people in providing course materials, teaching, and tutoring.

Other prominent research arenas include the Centre for Research into Autism and Education (CRAE) at University College London (UCL), whose former director, Liz Pellicano, has led the way in involving autistic people in setting a research agenda through the shaping autism

research series of seminars. Other autistic-led research initiatives worthy of mention include the Participatory Autism Research Collective (PARC) – whose aim is to build a community of those who wish to see more significant involvement of autistic people in autism research – and the team of primarily autistic researchers responsible for recent surveys of support for autistic students at university and in colleges of further education in England.

Besides the Kings College Institute of Psychiatry, Kings College has been involved in examining the ethical basis of autism research, hosting an ethics discussion group including autistic activists, ethicists, and philosophers as well as autism researchers in an endeavor which led to the conference Autism, Ethics, and Society held at UCL in 2010.

The Autism Research Group (ARG) at City University, London, has also led medical research in attempting to establish the neurobiological and genetic underpinnings of the cognitive and psychological differences in Autism.

The open access academic journal “Autonomy” (the Critical Journal of Interdisciplinary Autism Studies) was first published in 2012 with Larry Arnold as Editor. Autonomy has probably published more contributions by autistic scholars than any other individual academic journal since it was founded (Arnold, Editorial, 2012).

Advocacy

The 1990s saw the beginnings of a backlash against the framing of autism without input from autistic people and with the growth of access to the internet during this period, this took on an international dimension as the ideas of Sinclair (2005) and others became available to autistic people in England. Significant in England at the time was the online facilities offered by Martijn Dekker (see ► [“Personal perspectives on Autism”](#)) which allowed groups of autistic people to discuss a variety of topics regarding self-help

and advocacy. From those beginnings, individuals who had initially met online started to meet face-to-face to achieve other aims. These movements drew upon the notion of “neurodiversity,” a term first coined by Judy Singer in 1998 to refer to the natural variation in neurotype. In parallel to Dekker’s mailing list, there were others centered upon other forms of neurodiversity such as dyspraxia. Mary Colley (a dyspraxic adult) was a significant figure in this discourse and instrumental in forming the Developmental Adult Neurodiversity Association (DANDA) in 2003 following dissatisfaction with the parent-led focus of the Dyspraxia Foundation charity, dyspraxia as a condition having strong overlaps with Autism. Many of the early members of this organization were also Autistic and went on to play significant roles in other autistic and neurodivergent movements including membership of the Disability Rights Commission neurodiversity action group established in 2005.

In 1999, the NAS saw its first autistic Council member (Richard Exley) and in 2001 saw its first Autistic Board member (Larry Arnold), whose appointment led to significant changes within the organization including constitutional amendment to ensure equal rights and greater participation for autistic people within the organization and significant changes to their public presentation and campaigning.

In 2005, a group of Autistic people were asking why there was no equivalent in Europe of Autreat (see ► [“Personal perspectives on Autism”](#)) (a retreat-style conference run by and for autistic people), a question which led to the introduction of a similar event in England known as Autscope. Initially with assistance and advice from Autism Network International (ANI) members Jim Sinclair and Patty Clarke, in its first year, it managed to attract an international attendance, from the USA, Israel, and with a strong presence from the Nordic Countries and the Netherlands. Autscope emphasized the importance of autistic people as an international community.

In 2007 a group of politically motivated individuals met together at Autscope which led to the

formation of the London Autistic Rights movement, launched at a meeting in City Hall London where the key speakers were Dinah Murray, Larry Arnold, and David Morris, the London Mayors senior disability policy advisor (Arnold, Provisional Front Page for Autreach, 2007). The group initially had a specific focus on the capital, with access to the Westminster Parliament; however, this led to a UK-wide focus and the formation of Autistic UK which is the only national campaigning organization in the UK run by autistic people.

Autistica was founded in 2004 as Autism Speaks UK by Dame Stephanie “Steve” Shirley. In 2009, it decided to end its links with the US Autism Speaks. Its aims are to *promote and fund* “medical research to understand the causes of autism, improve diagnosis, and develop new treatments and interventions.”

In 2008 the founders of US-based Autism Speaks toured to promote the organization in the UK. This was vigorously opposed by autism rights campaigners who saw the organization as erasing autistic identity and rights. Of significant import was the Tree House (currently Ambitious about Autism) annual lecture. Tree House had inadvertently invited Bob and Suzanne Wright, the founders of Autism Speaks. In order to balance the expression of opinions, they commissioned Autreach to make a video to be shown at the event. The video called “Something About Us” (Murray and Benstock 2007) consisted of a collection of autistic people – not all of them verbal – presenting individual segments about the positive aspects of autism, to counter the negative stereotypes and pity invoking narratives of hard-line organizations committed to the elimination of autism.

An example of the progress resulting from such dialogues was the National Autism Project established in 2015 with the aim of providing “authoritative recommendations on those aspects of autism research and practice that have demonstrable effectiveness in benefiting autistic people and their communities.” Dinah Murray’s own advisory team of autistic people subsequently became the autistic advisory panel for the whole project, marking a significant breakthrough in

terms of the input of autistic people to a national autism initiative.

Current Issues and Controversies

Gender

Autism was once thought of as a predominantly male phenomenon with an oft-quoted ratio of four males to one female (and higher in the so-called “low-functioning” individuals). This was defended on the basis that these were the research findings which has led to the Extreme Male Brain Theory of autism (op cit). This has been much criticized from a feminist perspective (Yergau op cit) as stereotyping the so-called traits of maleness.

Behavioural Approaches to Autism

For the most part, the UK has adopted an eclectic approach to “intervention” and education, including the NAS’ SPELL (Structure, Positive, Low arousal, Links) TEACH (Teaching, Expanding, Appreciating, Collaborating and Cooperating, Holistic), Social Stories™ and counseling, in contrast to the predominance of ABA (Applied Behavioral Analysis) in the USA. ABA, however, has found its strong proponents in the Treehouse School (op cit). Mentoring has been found to be of value in higher education and employment and an autistic mentoring project (the Cygnet Project) was developed by London South Bank University led by Nicki Martin and Damian Milton.

Pseudoscience and Cures

Ever since the psychodynamic approach to autism was challenged by Bernard Rimland (1964), there has been an increasingly biomedical focus on Autism in some quarters prompted much by Rimland’s later work at the Autism Research Institute (USA), whose findings have been met with some skepticism elsewhere. Undoubtedly the most damaging controversy to emerge initially in England was the Measles, Mumps, and Rubella (MMR) vaccine scare which was bolstered by the since retracted and discredited study of Andrew Wakefield (Flaherty 2011). Since then there has

been an explosion in alternative medicine and the promotion of nonvalidated and potentially dangerous “cures.”

Employment

Historically, it is likely that autistic people found it easier to get work, but in an increasingly demanding environment this is no longer the case. Notwithstanding the potential problem of successful autistic people being underdiagnosed, there is now substantial evidence of high unemployment of autistic people even among those who are highly qualified. A great deal of this can be attributable to the structural exclusion of autistic people through advertisements and selection processes, which generally reflect those traits that autistic people are less likely to have.

There have been numerous attempts, such as the NAS prospects service, to provide employment support for individuals to help integrate them into the workforce and to keep positions in a highly socialized and rapidly changing environment. Likewise, there have been approaches concentrating upon the strengths of autistic people in recruiting for example software engineers and testers. Economic cases have also been made out for the costs of excluding autistic skills.

Recommendations for successful employment involve creating less sensorially stressful working environments and job mentoring through the social aspects of employment.

Legal Perspectives on Autism

Discrimination on the grounds of race and gender in England had been outlawed by UK legislation in 1965 and 1975, respectively. However, it was not until the Disability Discrimination Act (DDA) 1995 that discrimination on the grounds of disability was made illegal (in respect of employment and the provision of goods and services). The DDA introduced the concept of “reasonable adjustments” for those with disabilities. The Special Educational Needs and Disability Act of 2001 extended the ban on disability discrimination and introduction of reasonable adjustments to the

education sector. In 2010, the Equality Act subsumed all previous UK disability discrimination legislation.

Although it took three decades for the law in England to treat disability on an equal footing to race and gender, this is only the beginning. Despite race discrimination legislation having been in place for many years, the Metropolitan Police Service was described as “institutionally racist” by the Macpherson Report of 1999. Institutional racism is likely to be endemic despite the efforts of antiracism campaigners and legislation. Even if disability discrimination is not endemic, and there are those who argue that it is, the legal requirement to provide reasonable adjustments is not fully complied with in many areas of society including higher education despite the legislative requirement being in place for more than 15 years. The first diagnostic acknowledgment of autism (in the DSM-III) was only 1 year before the legislative objective to achieve inclusive education was enacted and the introduction of the process around SEN. Although both covered autism, there was likely to be a delay in achieving both objectives in comparison to well-established disability categories.

The Autism Act 2009 is the first autism-specific law in the world and first law specific to a particular disability in England. This Act makes imposes certain requirements on local authorities in relation to provision for autistic adults and required the Government to produce an adult autism strategy. The first Adult Autism Strategy was produced in 2010 and updated in 2014. Unfortunately, despite the efforts of those pushing for autism legislation, the Act does not cover children and young people which might have helped autism “catch up” with other SEN categories in education. And as with previous legislation (e.g., the Education Act 1981), no additional funding was forthcoming from Government for implementing the Autism Act provisions.

The Community Care Act (1990) modernised the pioneering Chronically Sick and Disabled Persons Act 1970 which had ushered in modern social service provision. This currently includes provision for services for autistic people including direct payments and personal budgets. Its

workings are however currently much restrained by the climate of austerity.

Synonyms

EPF model

Definition

The enhanced perceptual functioning (EPF) model of autism proposes that superior function and increased independence of auditory and visual perceptual processes are responsible for the distinct pattern of cognitive, behavioral, and neural performance observed in autism. The EPF model emphasizes the primacy of perceptual processes, rather than social or higher order cognitive processes, in giving rise to the autistic phenotype.

Initially proposed by L. Motttron and colleagues as an alternative to the weak central coherence (WCC) model of perceptual functioning, the EPF outlines eight principles of perception in autism:

1. More locally oriented perception is the default for individuals in autistic populations relative to typical populations.

2. Neural complexity is inversely related to performance in low-level perceptual tasks.
3. Early atypical behaviors regulate perceptual input.
4. In autism, primary and associative brain regions involved in perception are atypically activated during social and nonsocial tasks.
5. Higher order processing is variable in autism and mandatory in typical development.
6. Perceptual expertise underlies savant syndrome.
7. Savant syndrome is an autistic model for subtyping within pervasive developmental disorder (PDD).
8. Enhanced functioning of perceptual brain regions may contribute to abnormalities in perception in autism.

Evidence in support of this model stems from the demonstration of enhanced visual functioning across multiple tasks (Caron et al. 2006) and enhanced brain activity in brain regions implicated in pattern processing in autism (Samson et al. 2011).

Entrepreneurial Model

Paul K. Cavanagh

Vocational Independence Program, New York Institute of Technology, Central Islip, NY, USA

Synonyms

Entrepreneurial supports; Supported employment; Supported work

Definition

The term Entrepreneurial Model refers to creation of a new business entity as a means of providing work for an individual, or a group of individuals, with a diagnosis of a developmental disability. In this model, the skills and interests of the individual, or a group of individuals, with an autism spectrum disorder are used as a basis for the creation of a new business. The goal of the endeavor is to create enough revenue from the business to both pay the workers with a disability and support staff who assist them. An advantage of the Entrepreneurial Model is that the work involved is specifically chosen to match with the skills and interests of the individual (or individuals) with an autism spectrum disorder. The biggest challenge for an Entrepreneurial Model is that it faces the same start-up costs and difficulties in reaching profitability of any new business endeavor.

An Entrepreneurial Model is one work option along a continuum of supported employment for individuals with a disability. In addition to the Entrepreneurial Model, the most common types of supported employment models are an individual placement model, an enclave placement model, and a mobile work crew.

Entrepreneurial Supports

Ernst O. VanBergeijk
Vocational Independence Program, New York
Institute of Technology, Central Islip, NY, USA
Threshold Program, Lesley University,
Cambridge, MA, USA

Synonyms

Self-directed support corporation supports; Self-employment supports

Definition

Entrepreneurial supports are supports that would enable individuals working under an

entrepreneurial model to become successful. Success would be measured by the self-directed business ability to generate enough revenue not only for salaries of the individuals on the autism spectrum in the corporation but also for salaries of the staff hired to help them with this endeavor.

Like any other business, support takes many forms. It can include help in developing a business plan, securing loans or funding for start-up costs, accounting support in terms of paying taxes and other payroll issues, as well as taking advantage of employer initiatives and tax incentives such as Work Opportunity Tax Credits, Small Business Tax Credits, and Architectural/Transportation Tax Deduction: IRS Code Section 190, Barrier Removal (Gerhardt 2009). Support can also be in terms of renting office space, buying furniture and equipment, and advertising the product or service. Job coaching may also be a necessary support for individuals on the spectrum under this model.

Prevocational supports may also be necessary for individuals who are working under an entrepreneurial model. Prevocational supports may include travel training on mass transit in order to reach work or business meetings. It may also include how appropriate dress and hygiene for the type of business the individual is engaged in. Independent living skills might include money management and budgeting skills for the individual (e.g., grocery shopping, bill paying, paying for lunch) on top of money management skills or supports for the business.

“Many people with disabilities, particularly those in rural areas where jobs are often scarce, have already created opportunities for themselves through entrepreneurship. In fact, according to the U.S. Census Bureau, people with disabilities are nearly twice as likely to be self-employed as the general population, 14.7 percent compared to 8 percent” (US Department of Labor and Office of Disability Employment Policy 2011). Small businesses account for 60–80% of the new jobs annually (US Department of Labor and Office of Disability Employment Policy).

Government supports for individuals with disabilities who are engaged in the entrepreneurial model often begin with Vocational Rehabilitation (VR) services and programs:

- The Social Security Administration's (SSA) Plan for Achieving Self-Support (PASS) program allows people with disabilities receiving SSI benefits to set aside money and resources to help achieve a particular work goal, including self-employment.
- The Ticket to Work program connects SSI and SSDI beneficiaries with Employment Networks (EN) for training and other support services needed to achieve their employment goals, including self-employment.
- More than 1,100 Small Business Development Centers (SBDC) offer free or low-cost counseling, training, and technical assistance to individuals seeking to start their own business in communities across the nation.
- The Service Corps of Retired Executives (SCORE), comprising more than 10,000 counselors at 389 offices nationwide, provides free small business start-up advice through one-on-one counseling, group workshops, and online resources.
- Local One-Stop Career Centers funded through the US Department of Labor's (DOL) Employment and Training Administration (ETA) assist people in training for and obtaining employment, including self-employment (US Department of Labor and Office of Disability Employment Policy 2011).

Enuresis

Fred R. Volkmar

Child Study Center, Irving B. Harris Professor of Child Psychiatry, Pediatrics and Psychology, Yale Child Study Center, School of Medicine, Yale University, New Haven, CT, USA

Synonyms

[Bed-wetting](#)

Short Description or Definition

It is typical in developed countries that toilet training begins in the toddler period and usually is completed by age 3; there is some variation in this age (and in toilet training) across cultures. Various factors can interfere with the process including motor difficulties, cognitive and social problems, and lack of motivation (any combination of which may be present in younger children with ASDs). When toilet training is not achieved or was once achieved and then lost, a diagnosis of enuresis is made.

Categorization

A distinction is made between primary enuresis (the child has never been fully trained) and secondary enuresis (the child had been trained for a prolonged period – usually at least a year). Night-time or nocturnal enuresis is much more common than the daytime form. Isolated and very occasional

episodes of bed-wetting, particularly in younger boys, may not merit either a diagnosis or treatment since there is an expectation that the problem be sufficiently severe as to merit attention (either because of frequency or because it serves as a source of distress). The diagnosis is not made in very young children and cannot be made if the voiding is due to medical problems.

Epidemiology

Longitudinal studies have shown that boys are more likely than girls to exhibit the problem. By age 6 years, the vast majority of children (90%) are dry at night, and this number continues to rise so that in adolescence (age 15) only about 1% of boys and 0.5% of girls have episodes of enuresis on at least a weekly basis. There is some suggestion of familial risk and association with both stress and psychosocial adversity.

Natural History, Prognostic Factors, and Outcomes

Spontaneous remission of bed-wetting is common and often occurs by age 7. It is typical in longitudinal studies that during a given year, about 15% of children will have their symptoms remit. Behavioral treatments are typically regarded as a first line of intervention. The presence of multiple risk factors in the child, stress, and psychosocial adversity can complicate intervention. Behavioral psychologists can be involved in situations where developmental delays are present to help both in an assessment of the child's potential for understanding and participating in a treatment program and in a broader analysis of any associated behavioral difficulties.

Clinical Expression and Pathophysiology

A range of theories have been proposed – from those that focus on anatomic abnormality, psychological or neurological immaturity, to psychodynamic explanations. Developmental delay is a risk factor, and some data suggest complex interactions of factors in pathogenesis. A genetic component can be present.

Evaluation and Differential Diagnosis

Laboratory analysis of urine (to rule out infection) is a first step. There is not a high yield from more medically invasive studies in the absence of an indication for the same. Those children who have both day- and nighttime difficulties are more likely to have anatomical or other physical problems. Sometimes enuresis can be associated with other medical conditions or medications. Urinalysis is an obvious first step in evaluation of enuresis, for example, to rule out urinary tract infection as a cause. In general invasive laboratory studies do not have a particularly high yield and would not be indicated unless other indications were present. Children who have problems in both night- and daytime may be more likely to exhibit structural or other problems of the urinary tract. Ultrasound evaluation is less invasive than past procedures.

At times enuresis may arise following other medical problems, for example, hyperthyroidism, although this is infrequent. A physical examination should look for potentially treatable underlying conditions. Associations to other factors, for example, nocturnal enuresis that follows administration of a new medication, should be explored as relevant.

Treatment

Two approaches have been used for treatment: behavioral and pharmacological. Behavioral treatments have long been used and combine aspects of classical and operant condition in the “bell and pad” approach. The child sleeps on a pad that, if it becomes wet, closes an electrical circuit and rings a bell, thus awakening the child. A majority of children do respond, and the response is frequently maintained after the treatment is discontinued. Other behavioral approaches include use of a timer to awaken the child periodically to void.

Drug treatments have included several agents. The tricyclic antidepressant imipramine has been used for many decades. An ECG is obtained at baseline and the dose of the medicine gradually increased. Many children respond positively. In

such cases periodic attempts to discontinue it should be made. The mechanism of action remains unclear.

A more recent pharmacological treatment has used desmopressin acetate (DDAVP) (an analogue of a pituitary hormone involved in kidney function). The agent frequently is associated with a positive response, but symptoms do tend to turn once the intervention is discontinued and various side effects can be noted.

In the absence of other indications, psychotherapy is not usually indicated.

Environmental Engineering/Modifications

Christine Barthold¹ and Jodi M. Duke²

¹Center for Disabilities Studies, University of Delaware, Newark, DE, USA

²Division of Special Education and disability Research, Fairfax, VA, USA

Definition

Environmental engineering/modification strategies, also known as *antecedent interventions*, are defined as changes to the immediate environment that allow the individual with ASD to process

stimuli, predict future events, and respond appropriately. The purpose of environmental engineering strategies is to provide additional information about the appropriate and expected response in any given situation (Neitzel 2009; Quill 1995). They are considered proactive strategies to prevent problem behavior and increase appropriate behavior before correcting strategies are needed (Bregman et al. 2005). Since they are preventative in nature, antecedent interventions are often considered very socially acceptable interventions (Radley and Dart 2016).

There are a myriad of interventions that fall under the heading of environmental engineering. Such interventions include, but are not limited to, social stories and video modeling, functional communication training, consistent scheduling, choice, and organization, and visual supports. These interventions are often used to prevent problem behavior, but can also be used to increase adaptive behavior and as academic supports for learners of all ages. It has also been suggested that environmental engineering may increase independence and generalization of learned skills (Quill 1995). The majority of studies on antecedent interventions, though, focus upon their use to decrease problem behavior, such as stereotypy or self-injurious behaviors (Neitzel 2009). Although used widely by educators and considered to be effective and easy to implement, there is comparatively little research on the effects of antecedent manipulations on the behavior of children with ASD.

Historical Background

Antecedent interventions have, in some way, been an important part of interventions for individuals with ASD throughout the short history of intervention for the disorder. Historically, researchers have focused on consequences when assessing and intervening for problem behavior, however (Wacker et al. 2006). Division TEACCH, considered by some to be the first program to provide structured interventions for individuals with ASD, has been incorporating environmental engineering strategies since the 1960s (Mesibov et al. 2005). Some antecedents found to influence

learning and appropriate behavior include how instructions are delivered, timing and scheduling of learning opportunities, and medical and physical issues.

In applied behavior analysis, the antecedents which evoke both problem behavior and appropriate responding are considered to be critical to intervention. There are two different types of antecedents to consider – those that signal responding will result in a reinforcer (discriminative stimuli), and those that make reinforcement more or less potent (Motivating Operations; Wacker et al. 2006). Tools such as antecedent-behavior-consequence (ABC) data collection and scatterplot data determine what types of environmental events evoke problem behavior and what environmental changes could prevent reoccurrence of these types of behavior (Bijou et al. 1968; Touchette et al. 1985).

Current Knowledge

Whatever form of environmental engineering is used, it should be universally accepted by the members of the individual's community and implemented consistently. Those strategies that are most socially valid are more likely to be implemented consistently. Therefore, any strategy should take into account the child's environment, preferences, and community at large (Quill 1995). Considering antecedents, as well as consequences, allows for more precise assessments and better tailored interventions overall (Wacker et al. 2006).

It is also very important that any strategy selected is age-appropriate, especially for older learners with more severe impairments. For example, a 16-year-old with a visual system that includes pictures of preschool cartoon characters may serve to stigmatize the individual and decrease opportunities for social interaction. A more socially appropriate alternative might be using pictures of the adolescent themselves or other individuals in the class (Wehman 2006).

Before making environmental modifications, a thorough functional behavioral assessment (FBA) should be conducted to determine what environmental variables reliably evoke problematic

behavior for the individual in question (Bregman et al. 2005; Umbreit et al. 2007). In FBA, detailed data are taken to determine both the environmental events and the consequences that might be maintaining problem behavior. In more difficult cases, a functional analysis might be conducted. Functional analysis consists of a series of short, tightly controlled sessions where situations which are hypothesized to evoke the problem behavior are recreated. Data are taken on the antecedents, problem behavior, and consequences. If specific situations, when compared to control conditions, do, in fact, evoke problem behavior, they are considered to be the function (Iwata et al. 1994). Hurl et al. (2016) conducted a meta-analysis comparing interventions derived from functional assessment and analysis to those developed without assessment. Interventions developed from functional assessment, and especially functional analysis, had much higher treatment effects than those without. FBA, including functional analysis, allows the practitioner to tailor the intervention to the function of the behavior being assessed.

Structural analysis (SA; Stichter et al. 2009) may also be of help, and implementation is very similar to a functional analysis. In SA, the consequences for problem behavior are held constant and the antecedents are systematically manipulated. For example, an interventionist might be interested in whether pictures or verbal prompts are more effective in increasing on-task behavior. In one condition, verbal prompts are presented to the individual and on-task behavior is reinforced by verbal praise. In the second condition, the same task is presented, but this time visual cues are used to prompt responding. Reinforcement stays constant for on-task behavior. The strategy that produces more on-task behavior across several presentations is considered to be the most effective of the two interventions being evaluated.

There are several types of environmental engineering strategies available to those who work with individuals with autism. For the sake of brevity, these will be broken into the following categories: (1) priming strategies, (2) physical environmental modifications, and (3) activity-based strategies. What follows should not be considered to be an exhaustive list of strategies that

utilize environmental engineering; instead, it should be considered to be a survey of the myriad of environmental engineering interventions that are available to the interested reader.

Priming Strategies

Priming strategies consist of instruction on how to behave appropriately in or preexposure to new or stressful situations. They are designed to provide advanced knowledge to the individual with ASD that allows him or her to predict what will happen in the future. Some examples of priming strategies include video modeling, Social Stories™, and functional communication training.

In a traditional priming session, an individual visits an unfamiliar situation (e.g., school) prior to entering the situation. For example, a student with ASD might visit the first-grade classroom he or she will attend before the first day of school. This allows the individual to become comfortable with the environment so that navigating that environment is less overwhelming. An example is provided by Koegel et al. (2003). Students experiencing difficulty in preacademic and academic situations were exposed to the day's lesson the night or day before the lesson was presented in class. This reduced problem behaviors such as stereotypic behavior, repeated requests for the bathroom, inappropriate verbalizations, and disruptive behavior. Many of the strategies that follow are used in conjunction with traditional priming to increase appropriate behavior and decrease stress. Orellana et al. (2014) found that a component package of priming interventions increased compliance with routine dental exams. Intervention included familiarizing participants with common dental tools, video models of dental exams, and explaining the dental procedure (Orellana et al. 2014).

High-Probability Request Sequences (Hi-P). A High-Probability Request Sequence, or Hi-P, is typically implemented when quick compliance with a less preferred task is required. With Hi-P, a series of requests with a high probability of compliance are presented in quick succession, with the low-probability request immediately following. The momentum built by engaging in high-probability tasks increases the likelihood of

engagement in the low-probability task (Mace et al. 1997). For example, a teacher may tell a student to do a series of easy responses such as touch their nose, clap their hands, and give them a high five. Once these easy responses are complete, the targeted instruction is delivered. In order for Hi-P to be effective, the interval between requests must be only a few seconds. Using strongly preferred items as reinforcers for compliance with a low-probability request is also critical to success (Mace et al. 1997; Radley and Dart 2016).

Video modeling uses a simple video of a social situation or task to teach the student how to complete the task or behave appropriately in a particular situation. The student watches this video several times and can pause, rewind, or otherwise manipulate the video model. The video model provides a concrete set of parameters for responding that can be viewed repeatedly to rehearse a social situation (Cihak 2011). Portable video modeling has recently been shown to be effective in a few studies, using iPad, iPhone, and iTouch technology and provides a unique opportunity for greater flexibility and modeling in the authentic environment (Carnahan et al. 2012). Recent research suggests that video models are effective in a variety of environments, with a variety of individual and across a wide variety of skills including social, communication, play, joint attention, academic, motor, and vocational (Acar and Diken 2012). It is considered to be an evidence-based practice according to the National Professional Development Center on Autism Spectrum Disorders (Franzone and Collet-Klingenberg 2008).

Social Stories™ are simple stories that are read by the individual prior to entering a social situation. The story highlights at a minimum what the individual should try to say or do and how their behavior affects others. According to Carol Gray, the developer of Social Stories™, the following minimum elements must be present: (1) descriptive statements, which present factual information about the situation; (2) perspective statements, which provide information about the emotions and behavior of others; and (3) directive statements, which guide the student regarding strategies to try in the situation (Gray 2000; Kokina and Kern 2010). These stories are always written as

suggestions for the student in order to encourage flexibility and generalized responding. Social Stories™ are reviewed by the individual before the challenging situation presents itself in a calm and nonthreatening environment (e.g., the social story is best read to the child right before lunch if the cafeteria is a problematic environment). Social Stories™ have been recognized by The National Autism Center as an evidence-based practice (Leaf et al. 2016).

Teachers and other practitioners report that Social Stories™ are an easy, cost-effective way to increase appropriate behavior and teach social skills, especially skills which require taking the perspective of others. Research on Social Stories™ is limited, and in most research, Social Stories™ have been most commonly used as one element of an intervention package; however, that which does exist suggests that Social Stories™ are best as brief interventions. According to Kokina and Kern (2010), those developed using functional behavioral assessment (FBA) data and addressing problem behavior versus complex social skills seemed to be most effective. However, Karkhaneh et al. (2010) found in their review of the literature that Social Stories™ increased behaviors such as game playing, reading comprehension, and reading and comprehending social situations. Individuals with moderate social skill problems and moderate reading ability seemed to benefit more from Social Stories™ than those with low social skills and lower reading ability (Kokina and Kern 2010). No evidence is available at present regarding the generalization and long-term maintenance of the effects of Social Stories™. The evidence base for Social Stories™ is at present rather small; however, its use as a brief intervention for individuals with higher communication and social skills is promising and Social Stories™ are being used in a wide variety of intervention settings (Kassardjian et al. 2014).

Functional communication training (or FCT) is a strategy in which the individual with ASD is taught to request preferred items or activities. These items are often identified as those requested through problem behavior in the past. Based upon the hypothesis that the majority of problem behavior is communicative in nature, FCT provides for a

more socially appropriate way to communicate wants and needs for individuals who may have limited expressive skills. In most cases, some sort of alternative or augmentative communication system, such as paper-based picture symbols or voice output device, is selected for functional communication training. The individual is then taught to manipulate the communication system to request preferred items that in the past triggered problem behavior. Research supports that replacing problem behavior with appropriate requesting skills can decrease the amount of problem behavior in individuals with ASD (Mancil 2006). For example, teaching a child to request a break rather than engage in self-injury can result in a decrease in the problem behavior and an increase in the likelihood that the child will request a break appropriately (Carr and Durand 1985).

Even when problem behavior is not a concern, *augmentative and alternative communication devices* (AAC) may be used for individuals without spoken speech. These devices range from low-technology (such as the picture exchange communication system or PECS; Frost and Bondy 2002) to sophisticated high-tech devices. As with all accommodations and modifications, the system is based upon a thorough evaluation of the child's needs. A qualified speech-language pathologist often evaluates the child and determines the best intervention method for that individual.

The Picture Exchange Communication System (PECS) is a common and well-known system for communication by individuals with ASD, although its use is not limited to just individuals with ASD. In PECS, individuals are systematically instructed to (1) hand their communicative partner a picture to request items, (2) to recruit attention if the communicative partner is otherwise engaged, (3) discriminate between cards, (4) increase complexity and combinations of cards, and (5) use picture cards to comment on the environment (Frost and Bondy 2002). A 2009 review of the literature returned over 30 articles showing the effectiveness of PECS. Although all presented positive results, many abandoned the protocol in the early phases, leaving the later and more sophisticated aspects of PECS untested. The authors suggested a number of research questions,

including research into generalization of the effects of PECS, using PECS with high-tech communication devices, and investigations into what elements of PECS affect the development of spoken speech for those who acquire it (Sulzer-Azaroff et al. 2009). PECS also offers users an exchange that closely resembles the interactive manner of a speech-based conversation; as the user hands the selected PECS icon to the receiver, they have the opportunity for reinforcement and engagement, which can be highly motivating (Bondy 2012).

One concern that researchers and practitioners previously expressed is that the use of PECS will preclude or delay the use of speech in users; this seems to have been resolved. The evidence supports that AAC enhances rather than suppresses spoken speech. Adding a qualified Speech-Language Pathologist to the treatment team increases the probability of success (Bondy 2012; Lerna et al. 2012). In this manner, PECS should be thought of as both an alternative and augmentative system. PECS has also been shown to be effective in addressing deficits in joint attention, imitation, and play skills in young children with autism (Lerna et al. 2014).

At present, there is a debate as to whether visually based communication systems (such as PECS and picture symbol-based devices, also sometimes called aided devices; Mirenda 2003) are better for individuals with ASD than more transient devices and systems such as signed exact english (SEE; also called unaided devices). The rationale is that picture-based symbols use the visual channel (considered to be a strength of individuals with ASD) are more static (i.e., they do not disappear) and resemble their referents. Recent research suggests that neither system is best for teaching functional communication; rather, choosing a system is an individually based clinical decision. Limited evidence suggests that for children who have more advanced fine motor imitation skills, sign may have the advantage of being easier to learn and generalized. However, these conclusions are based upon small studies with identified methodological difficulties (Tincani 2004).

Voice output communication devices (VOCA; Mirenda 2003) are an often chosen modality for

individuals on the autism spectrum. A VOCA produces either a synthesized or recorded vocalization when an individual presses a button. These buttons usually have some sort of graphic display. For example, pushing the button with a picture of a drink may produce a sound file where a voice says, "I want a drink." According to Mirenda (2003), VOCAs have the potential to encourage more social interactions. Individuals may respond more readily to an auditory bid for interaction than a sign or pictorial one. There is some evidence that VOCA devices may assist the functional communication of individuals with ASD in school or clinic settings. However, the research on VOCA for children with ASD is somewhat sparse, especially in the area of generalization to home and community (Mirenda 2003). Still et al. (2014) reviewed the literature on Speech Generating Devices (SGDs) and found few studies on the use of tablets and apps. Most studies focused on a small number of functional responses such as requesting preferred items or attention. Therefore, it is unknown whether SGDs have the capability to promote large vocabularies in individuals with autism. It is important to understand the variables that predict success with more high-tech communication devices as well as what variables affect the selection of a functional communication system.

The continually evolving nature of technology requires a careful eye on the research to support it. Further research is critical in this age of iPads, iPods, and apps that increase communication for children with ASD. Tablet computers such as iPads have gained popularity in the past few years. They are readily available and used by people with and without disabilities, thereby reducing the stigma of having an assistive device. At least initially, parents and family members prefer tablets to PECS and other portable devices (Allen et al. 2016). The multifunctional nature of tablets allows for one small machine to deliver instructions, visual cues, video models and serve as a SGD (e.g., Vandermeer et al. 2013). It is important to note that just buying a tablet for a child with autism isn't enough to increase communication and other skills. But paired with individualized instruction and evidence-based practices for

teaching, the tablet can be a tool that enhances learning and social interaction (Allen et al. 2016).

Whatever functional communication system is used, the *representational competence* of a learner must be taken into consideration. Representational competence refers to the ability of a learner to infer meaning from some sort of symbol (Mineo Mollica 2003). Although line drawings are a popular way to create schedules, they are in fact very advanced and abstract representations. While individuals with autism have demonstrated the ability to derive meaning from abstract line drawings, they seem to rely more on the resemblance of that drawing to concrete items to derive meaning (Hartley and Allen 2014). For individuals who do not respond to typically used picture symbols, it might be better to use a more concrete representation such as legible photographs or, in some cases, the actual object (Mirenda and Locke 1989).

Setting Modifications

Setting modifications, such as work systems, visual schedules, and organization and structure, refer to arrangements of the physical settings encountered by learners with ASD so that salient features of the environment are visually clear and so that the individual with ASD clearly knows what to do in each environment. The majority of setting modifications are visual; however, some are auditory in nature or a combination of both (e.g., timers, transition music). Division TEACCH uses many setting modifications, such as color coding, stations, and visual cues, to reduce the amount of verbal interaction (Mesibov et al. 2005). The rationale for using visual setting modifications is that most individuals with ASD tend to more easily process stimuli visually rather than verbally.

Visual schedules function in much the same way as a “to-do list.” In a visual schedule, the events of a person’s day (or in most cases, a subset of the person’s day) are arranged on a schedule either horizontally or vertically (Hume 2008). Visual schedules may also be created for specific tasks. For example, the task of hand washing may be broken into its component parts and a visual of each part may be placed in the bathroom to prompt the appropriate hand-washing sequence.

It allows the individual with ASD to process and organize his or her time. In most cases, pictures are used to represent each of the activities; however, words can be used for higher-functioning individuals and actual items are sometimes used for individuals with less processing and representational skill. As each item is completed, the picture is removed and put away, signaling its completion.

When creating a visual schedule, it is important to consider the needs of the child. For example, a younger or less experienced learner may need to have a simple schedule that consists solely of what is happening now and what will happen next. A more advanced learner may be able to process a full day’s schedule. In the case of a task-based visual schedule, a less experienced learner might need a more detailed analysis, whereas the more advanced learner might be able to anticipate and chunk information into a single visual cue. Examples of how to create and use appropriate visuals are available (see Hodgdon 1998). Representational competence, described earlier in this article, should be considered as well.

Although visual cues are often associated with schedules and/or task sequences, photographs and other types of picture symbols can be used to prompt appropriate behavior in a number of ways. Many individuals with ASD respond well when there are visual cues in the environment that can help them understand how to respond and when. Labels with picture symbols may also be used to describe expectations in the environment. For example, a child’s place at the dinner table might be signaled with their picture on a placemat. The child is then instructed to find their picture and sit at that chair. West (2008) found that pictorial cues were more effective than verbal prompts in teaching a variety of skills to individuals with ASD. These skills both generalized to novel skills and maintained over time (West 2008). Knight et al. (2015) reviewed the literature on visual schedules and used the criteria established by Horner et al. (2005) to determine whether visual schedules should be considered an evidence-based practice to increase, maintain, and generalize skills for individuals with autism. Their findings support the consideration of visual schedules as an evidence-based practice for

individuals with autism and suggest that they can be used to teach transition behaviors, improve latency from task direction to task initiation, and decrease prompts required for transitions.

Visual cues seem to be effective for individuals with autism across the lifespan (Hume 2008) and for teaching a variety of skills. For example, Ganz et al. (2008) used visual social scripts and cues to “be quiet” to increase appropriate social statements and reduce perseverative statements in three elementary children with ASD. Modest generalization of appropriate untrained social statements was observed as well.

Spriggs et al. (2015) examined the use of iPad technology with visual schedules to support four students with autism as they transitioned between activities. They found that the portable technology motivated the students, was age appropriate, socially acceptable, was readily available, and afforded the opportunity to embed video modeling within the visual schedules. While two of the students became independent with their tasks using the visual schedules with embedded video modeling, two required the additional support of video chunking. All four students high levels of generalization when the video models were faded from the visual schedules.

Organization of elements in the environment is also considered to be an important part of environmental engineering for individuals with autism. Some advocate for more ambient lighting, reduced distractions, and less stimulating environments. These changes are introduced to reduce the amount of stimulating sensory input and allow the child with autism to focus upon those important parts of the environment (Kluth 2003).

Organizing the environment by activity and reducing clutter is another element of environmental engineering. For example, a teacher might use bookcases to cordon off the reading area and surround the area with red tape. The activity area may include active toys and may be surrounded by blue tape on the floor. These supports are designed to give the individual with autism more information about what is expected in certain areas of the classroom or home. These types of visual supports are considered to be critical to the structured teaching strategies developed by division TEACCH

(Mesibov et al. 2005). Some interventionists have called eliminating clutter and extraneous stimuli *sterilizing the environment* (Carbone 2003).

As with all interventions, these supports should be individualized; some individuals will respond better to quiet environments while others work better with background noise (Scheuermann and Hall 2008). Clear and consistent scheduling is also considered to be a critical environmental support. Many individuals with autism have difficulty processing open-ended instructions or activities; therefore, supporting the understanding of the beginning or end of an activity can help to increase appropriate behavior. Visual schedules can assist with this task, as well as timers and cues such as music during transitions (Scheuermann and Hall 2008).

Any organizational strategy must be flexible; that is, the individual with ASD should be prepared in advance for changes or out-of-the-ordinary events. For example, a birthday party might be put on the calendar, or a surprise icon might be placed on the visual schedule to signal an unexpected event. While providing clear visual cues and eliminating extraneous stimuli from the environment are considered to be best for individuals with ASD, there is little research to support effectiveness at this time. Several literature searches with terms such as “classroom organization and autism,” “environment and autism,” and “environmental organization and autism” returned no empirical articles. Studies that investigate the effects of a carefully organized physical environment need to be conducted.

Activity-Based Strategies

Activity-based strategies are those that are embedded into everyday activities and provide modifications or accommodations for individuals with ASD. Some examples include supporting academic, modifying task, incorporating preference and choice, and prompting techniques.

A well-known intervention from TEACCH is the *work system*. In the work system, a task is broken down into its component parts and visuals are created that communicate to the learner with ASD (1) what is to be done, (2) how much work needs to be done, (3) when he or she is finished, and (4) what the person should do once the work

is complete. The goal of the work system is to increase independence in children with ASD and decrease prompts. It has been shown to be effective with elementary and middle school students and can be used to teach a myriad of tasks including vocational, self-help, and transitions (Hume and Carnahan 2008). Boyd et al. (2014) found that preschool-aged children with autism made gains or reductions in autism characteristics using the TEACCH system. An interesting finding in this study was that students with lower cognitive abilities demonstrated the most significant gains.

In the first study to examine the effects of the TEACCH work system on task accuracy and the use of newly acquired skills, Hume et al. (2012) found that the TEACCH work system increased student accuracy and reduced prompt dependency for three first grade students with autism. These results generalized across settings including the general education setting, where the TEACCH systems were never used. This finding offers promising evidence that skills could be taught in a special education setting using the TEACCH work systems and would generalize to inclusive, general education settings.

Academic supports and task modifications are those supports that allow an individual to be successful at a task. Some of the core characteristics of ASD (e.g., communication, restricted, and repetitive interests) can directly affect academic achievement (Fleury et al. 2014). These supports might include visual cues, such as reducing the amount of visual stimuli to isolate visual tasks (such as folding a piece of paper to cover up additional questions on a test). Other visual supports include highlighting pertinent information, color coding salient information, etc. Other modifications may include frequent proactive breaks (i.e., breaks set at preset intervals as opposed to in response to agitation) or using a task analysis, where a task is broken into its component parts and taught in a systematic fashion. Considerations for creating academic and task modifications are available in Vaughn and Bos (2012). Visual supports such as the visual schedules described above can also be used to modify tasks.

More students identified as having ASD are continuing their education beyond K-12.

Accommodations for individuals with ASD mirror those offered to others with disabilities in higher education, such as extended time and alternative formats of assignments (Gelbar et al. 2014). This points to an increased importance of teaching to generalization in postsecondary environments. Many of the antecedent interventions presented throughout this article, such as priming, clear expectations, and visual supports, are beneficial with older learners with ASD (Fleury et al. 2014). More research is needed, however, on how to best support learners with ASD in secondary and post-secondary settings.

Incorporating preference and choice can increase the success of an individual with ASD. Those items that a child is more likely to choose are typically the most reinforcing (Mason and Egel 1995) yet individuals with autism are making fewer daily choices than those without autism (Mehling and Tasse 2015). Using preferred items for teaching may also increase the likelihood of attention. Giving individuals simple choices, such as the order in which to complete a task, can decrease problem behavior and increase more socially appropriate behavior (Smeltzer et al. 2009; Ulke-Kurkcuoglu and Kircaali-Iftar 2010) and improve social outcomes such as community inclusion and interpersonal relationships (Mehling and Tasse 2015). Rispoli et al. (2013) found that although rates of challenging behavior were lower for all choice conditions than for no choice conditions, offering students with ASD choices across activities (i.e., the choice of a math or reading task) resulted in a greater decrease in challenging behaviors than offering choice within activities (i.e., the choice of using a pen or a pencil).

There are many different types of assessments of preference. Often, teachers and caregivers will give families a checklist or open-ended questionnaire to complete. Professionals, however, should be aware of respondent bias when questionnaires are used. Free-operant preference assessments consist of giving a child free access to a limited number of items. Those manipulated or consumed most frequently are considered to be the most preferred. In a forced-choice preference assessment, items are presented in pairs and the child is asked to choose which one they would like to manipulate or

consume. It is important to note that different types of preference assessments may yield different results; therefore, multiple modalities of preference assessment may be in order when finding preferred items proves difficult (Kodak et al. 2009).

Related to choice is the notion of environmental enrichment. In environmental enrichment, additional items are provided that allow the child to be appropriately engaged in activities as opposed to engaging in repetitive, stereotypic behavior (Neitzel 2009). Visual cues, items to hold, and timers may also be effective interventions for difficulties with transitions and wait time. Ringdahl et al. (1997) found that systematically providing environmental enrichment in the form of preferred items to manipulate reduced self-injurious behavior in three participants with developmental disabilities. A recent review of the literature found environmental enrichment to be an effective strategy for reducing stereotypic behavior in individuals with developmental delays (Lancioni et al. 2009).

Prompts are additional instructions provided to a child with autism that allow them to be successful in activities. The prompts and prompting sequence is tailored to the learner with ASD. Common strategies include the least-to-most prompting sequence, where prompts are introduced in order of intrusiveness (typically from verbal to hand-over-hand guidance) until the child is successful. Most-to-least prompting reverses the sequence and systematically fades prompts as the learner needs less and less assistance to be successful. In time delay, the teacher gradually increases the time between the instruction and the prompt until the learner anticipates the prompt (Alberto and Troutman 2009). The evidence base supports the use of prompting for most behaviors and individuals of all ages (Neitzel and Wolery 2009).

Future Directions

Anecdotal and empirical evidence support the use of environmental engineering for individuals with ASD; however, additional empirical evidence is needed for specific environmental engineering strategies. Antecedent-based interventions are

popular among practitioners because they are easy to implement, considered to be cost-effective and are perceived to be effective. Although there is much evidence that antecedent-based interventions are being utilized with individuals on the autism spectrum, much more research should be devoted to investigating why and how these interventions are effective.

The best-researched environmental engineering interventions seem to be those surrounding functional communication training, especially PECS, and priming. Many interventions have a rapidly growing evidence base, such as Social Stories and video modeling. Others, such as environmental arrangements and academic supports, have little evidence to support them. There is a marked paucity of literature on supporting adolescents and adults, especially those choosing postsecondary education. It seems as if, in many ways, “the devil is in the details.” At present, which interventions work best for specific students and the details of implementation seem to remain the domain of clinical judgment. Evidence-based guidance for clinicians may assist them in making more efficient, individualized decisions for intervention. Considering environmental engineering is deemed important in many respected books and training manuals, and more evidence is needed to support its use.

Environmental Risk Factors for Autism

²Department of Public Health Sciences and the MIND Institute, University of California, Davis, Davis, CA, USA

Definition

Environmental risk factors for autism may be broadly defined as any nongenetic contributor

to the risk of autism and include reproductive-, dietary-, chemical-, and demographic-related exposures.

Historical Background and Evidence for a Role of the Environment

Environmental factors have been explored as contributing to the development of autism spectrum disorders (ASD) since the condition was first characterized in 1943 by Dr. Leo Kanner, who stated that children with autism had “very few really warm-hearted fathers and mothers” (Kanner 1943). Soon after, the term “refrigerator mother” was coined, which blamed the child’s behaviors on emotionless parenting (Bettelheim 1972). This explanation has since been disproved, and though the focus shifted from environmental factors for some time, research from other areas has clearly demonstrated a role of the environment in ASD.

Early twin studies in the 1970s and 1980s demonstrating non-concordance of diagnosis in monozygotic twins provided support that the environment, in addition to genetics, plays a key part in the etiology of ASD (Folstein and Rutter 1977; Steffenburg et al. 1989). Over time, estimates of environmental contribution to ASD have increased, with current estimates indicating that the environment is responsible for between 50% to 55% of ASD genetic variance (Hallmayer et al. 2011; Sandin et al. 2014).

Evidence of structural and functional brain differences in individuals with ASD point to the prenatal and perinatal developmental period as a key vulnerable window for risk of ASD. The critical stages of neurodevelopment within early gestation provide a period of increased susceptibility to environmental exposures which may confer risk of ASD. Two historical examples have demonstrated the role of environmental prenatal exposure on ASD risk. The use of thalidomide for morning sickness in the 1950s demonstrated a marked increase in the risk of ASD, far greater than estimates from that decade (Lotter 1967). Prenatal use of valproic acid, an antiepileptic drug, has also been shown to increase ASD risk, in children whose mothers used anticonvulsants

during pregnancy, as reported in multiple studies (Moore et al. 2000; Rasalam et al. 2005). In addition to these historical examples, the increasing prevalence of ASD lends support for continued investigation into environmental risk factors. While improved awareness, social acceptance, and shifts in diagnostic criteria explain part of this increase, analyses have suggested steep rises in incidence that cannot be fully explained by these artifacts of societal changes (Hertz-Picciotto and Delwiche 2009; King and Bearman 2009). One study found that up to 40% of the rise in prevalence in Denmark could be due to yet unknown environmental causes (Hansen et al. 2015).

Current Knowledge

Prenatal and Perinatal Factors

Maternal Environmental Markers

One well-studied and consistently replicated risk factor is parental age. Increased maternal and paternal age are each independently associated with ASD risk. Maternal age greater than 35 is often associated with a substantial increase in risk compared to women younger than 25 according to a meta-analysis (Sandin et al. 2012). Paternal age greater than 40 is also associated with increased risk of ASD in offspring (Durkin et al. 2008). In addition to being a proxy for age-related genetic changes in germ cells, environmental explanations for this risk range from increasing toxin loads in both mother and father to increased risk of autoimmune disorders and rates of pregnancy complications in mothers (Shelton et al. 2010).

A few environmental factors may represent markers or proxies, as opposed to true risk factors. These include seasonality, or season of conception or birth, which has been associated with ASD risk (Zerbo et al. 2011), with some variation in findings. This may be due to seasonal exposures like pesticide use or infections. Inter-pregnancy interval (IPI), or the time between the live birth of one child and the conception of another pregnancy, may also represent a proxy measure. Several population-based investigations reported

that shorter IPIs of less than 12 months had odds ratios ranging from 1.44 to 3.39 compared to IPIs greater than 36 months (Cheslack-Postava et al. 2011, 2014; Durkin et al. 2015). This association may be a result of the depletion of essential maternal nutrients, such as folate, which can take up to a year postpartum to replenish (O'Rourke et al. 2000). Other mechanisms potentially responsible for this association include maternal stress and inflammation; however, no studies to date have examined these factors as potential mediators of the IPI-ASD association. Long IPIs of greater than 120 months have also been associated with ASD risk (Cheslack-Postava et al. 2014; Durkin et al. 2015), but overall findings remain inconsistent.

Immune Factors

A growing body of evidence points toward maternal immune system response during the prenatal period as an etiologic area of interest. One study reports that maternal hospitalizations due to infection are associated with a 30% increase in ASD risk, regardless of which trimester the hospitalization occurred (Lee et al. 2015). Other epidemiological investigations support these findings (Zerbo et al. 2015). However, evidence distinguishing infection type (viral vs. bacterial) and timing remains inconsistent.

A recent study examined maternal influenza and ASD in a population of 196,929 children and found that there was no significant association between ASD and physician visits for influenza or an influenza vaccination (Zerbo et al. 2017). The CHARGE (CHildhood Autism Risks from Genetics and the Environments) study (Hertz-Picciotto et al. 2006) also found no association with maternal influenza but did find an increase in odds of ASD with maternal fever in the second trimester (Zerbo et al. 2013). Consistent with this finding, a large prospective Norwegian study observed more than a tripling of risk associated with three or more fever episodes after 12 weeks' gestation (Hornig et al. 2018).

Regardless of infection type, there are several studies which describe altered immune marker concentrations during gestation with increased risk of ASD. Women with elevated levels of circulating cytokines and chemokines, such as

interleukin-6 (IL-6), during pregnancy were more likely to have a child with both ASD and intellectual disability (Jones et al. 2017). IL-6 is secreted within the body to stimulate immune response and is known to aid in fighting infection; unlike most interleukins, it readily crosses the placenta into the growing fetus's circulation (Zaretsky et al. 2004). Investigators also found that high concentrations of C-reactive protein, an inflammatory biomarker, within maternal serum during pregnancy increased the risk of ASD by 43% in a sample of nearly 1.2 million mother-child pairs (Brown et al. 2014).

Medication Usage

In addition to valproic acid, recent studies suggest that prenatal use of other medications may also influence ASD risk. Selective serotonin reuptake inhibitors (SSRIs), commonly used to treat depression, have been associated with ASD in several studies. Mothers taking SSRIs during early pregnancy had between a 1.4- and 1.8-fold increase in risk of having offspring with ASD (Brown et al. 2017). It is possible that maternal depression and mental illness, both associated with increased ASD risk in the child and indicated for use of SSRIs, are responsible for this finding (Brown et al. 2017) (a situation known as "confounding by indication" where the condition rather than the treatment represents the true risk factor). However, further research is needed to clarify the associations between antidepressants, maternal mental illness, and ASD.

An important consideration in studies of medication use and ASD is weighing the potential risks versus the benefits, as untreated conditions may also influence risk, and public health messages need to be carefully presented to pregnant women only after research has consistently demonstrated associations in separately replicated studies.

Recently, prenatal acetaminophen use has also been examined in association with ASD. Two large studies observed that higher maternal use of acetaminophen during pregnancy was associated with increased risk of ASD or autism-like symptoms, as well as attention deficits and hyperactivity (Avella-Garcia et al. 2016; Liew et al.

2016). Both studies found that earlier and more frequent use during pregnancy was associated with higher risk. However, these findings require replication and further study, careful selection of comparison group, and clearer details on dosage and frequency of use.

Pregnancy Complications

Several pregnancy complications have been repeatedly associated with increased risk of ASD. Metabolic complications, like gestational diabetes, have been associated with a consistent increase in risk of ASD in several studies (Lyll et al. 2012; Xiang et al. 2015; Li et al. 2016; Connolly et al. 2016), as have preeclampsia and maternal obesity (Walker et al. 2015; Sanchez et al. 2017). Numerous studies have implicated complications in the perinatal period, with risk of ASD. Delivery complications such as fetal distress, birth asphyxia, and placental insufficiency are all potentially associated with increased ASD risk (Hultman et al. 2002; Gardener et al. 2011), though associations with individual complications are less consistent (Getahun et al. 2017). For neonatal complications, a range of factors have also been examined in association with ASD, with greater consistency for increased risk associated with low birth weight (Mann et al. 2010), preterm birth (Buchmayer et al. 2009), and potentially, complications relating to hypoxia (Gardener et al. 2011). Evidence suggests a combination of several of these factors in the prenatal and perinatal periods, leading to suboptimal birth, could additively be responsible for a significant association with ASD (Lyll et al. 2012). Impaired fetal development assessed at birth may reflect prenatal maternal obstetric complications, and both of these may be related to further upstream etiologic factors, including environmental insults.

Folic Acid and Related Nutrients

The beneficial effects of folic acid supplementation in reducing neural tube defects are well-established, but the relationship of pre- and perinatal folic acid and multivitamin supplementation on ASD outcome has been more recently suggested. Most studies evaluating the association

between periconceptional intake of folic acid and ASD reported a reduced risk of ASD or autistic traits. Folic acid supplementation was shown to confer a greater risk reduction among mothers and children with genetic susceptibility for less efficient folate metabolism (Schmidt et al. 2012). Additionally, recent studies report that high folic acid intake, particularly during the first trimester, reduced the risk of ASD due to air pollution and prenatal pesticide exposure (Schmidt et al. 2017; Goodrich et al. 2018). The evidence based on measured folate levels during pregnancy and ASD risk is still unclear since studies have reported nonsignificant associations but concurrent significant associations with folic acid supplementation (Braun et al. 2014a; Steenweg-de Graaff et al. 2014). A potential explanation for this lack of association with the measured levels could be that high folate levels later in pregnancy offer no protection against ASD, as suggested by three studies reporting protective effects only from higher folic acid intake and supplementation within the window of a few months before to about 6 weeks after conception (Schmidt et al. 2012; Suren et al. 2013; Bjork et al. 2017). Thus, there is a need for additional studies to identify the critical windows of exposure that link biologically measured folate to ASD.

Other Prenatal Nutrients

Limited research has investigated other maternal dietary factors in association with ASD, though the importance of maternal diet in neurodevelopment is well-established. There is increasing interest in the role of vitamin D deficiency in the pathogenesis of ASD, given the role of vitamin D in immune system functioning and neurodevelopment. Two studies from Nordic countries, one that assessed clinical vitamin D deficiency in pregnancy and another which assessed the level of 25[OH]D₃, a biomarker of vitamin D exposure, in midpregnancy reported increased association with ASD and Social Responsiveness Scale (SRS) scores, respectively (Magnusson et al. 2016; Vinkhuyzen et al. 2018). Additionally, studies that measured 25[OH]D₂ in maternal blood at the first and second trimesters, and in neonatal blood spots, reported increased

odds of ASD diagnosis with low prenatal vitamin D levels (Chen et al. 2016; Vinkhuyzen et al. 2017; Fernell et al. 2015). Two studies examining prenatal iron intake reported a reduced risk of ASD with iron supplementation (Schmidt et al. 2014); however, reduction was also seen for multivitamin intake with or without iron or folic acid (DeVilbiss et al. 2017). Maternal dietary intake of polyunsaturated fatty acids (PUFAs) has been associated with reduced risk of ASD in one US cohort (Lyll et al. 2013), while a cohort study from Spain found that maternal seafood (including ocean fish) consumption, a key source for these fatty acids, was associated with fewer ASD symptoms as measured by the Childhood Asperger Syndrome Test (Julvez et al. 2016). However, an analysis of prenatal plasma levels of major classes of PUFAs, omega 6 and omega 3, found an increase in autistic traits as measured by a shortened version of the SRS for the former and no association for the latter (Steenweg-de Graaff et al. 2016). Prenatal fish consumption or fish oil supplement use was not associated with ASD in another large Norwegian cohort study (Suren et al. 2013), demonstrating conflicting findings across the available studies.

Continued research into these and other dietary factors may be fruitful in identifying modifiable risk factors for ASD, as well as factors that interact with other ASD risk factors (Schmidt et al. 2017; Goodrich et al. 2018).

Alcohol and Smoking

Both alcohol and tobacco smoke are known risk factors of adverse perinatal and neonatal outcomes. The current evidence shows a lack of association between prenatal exposure to tobacco and ASD. Analysis using national-level ASD monitoring data in the US found no overall associations and a suggestive increased relationship with higher-functioning ASD (Kalkbrenner et al. 2012), but a more recent meta-analysis using studies from multiple countries showed null associations (Rosen et al. 2015). There are fewer studies assessing the effect of prenatal alcohol exposure on ASD, but the most recent reports based on US and Danish data show null associations (Eliassen et al. 2010; Singer et al. 2017). For these lifestyle

factors, underreporting is likely a major problem; furthermore, many of the studies have not adequately adjusted for confounders. Studies with biomarkers and proper control for confounding are needed to fully resolve the potential impact of these substances on ASD.

Environmental Chemicals

The Toxic Substances Control Act's (TSCA) registry of chemicals created by the US Environmental Protection Agency (EPA) currently lists ~85,000 chemicals registered for commercial use, with new alternatives for problematic substances added each year. Despite historical evidence of teratogenic and neurodevelopmental problems due to mercury and lead, only a fraction of these chemicals have been tested for adverse effects on neurodevelopment. Some of these chemicals can cause downstream effects on fetal neurodevelopment through maternal hormonal or immune system-mediated pathways, whereas others can directly cross the placental barrier to affect the growing fetus. An increasing number of studies are focusing on exposure to these chemicals in association with ASD, given suggestive findings for other related outcomes.

Air Pollution

Prenatal exposure to air pollution has emerged as a risk factor for ASD over the last decade. Several epidemiological studies have evaluated the risk from estimated levels of hazardous air pollutants (HAPs), criteria air pollutants (nitrogen dioxide (NO₂), ozone, particulate matter less than 2.5 μ (PM_{2.5}), 10 μ in diameter (PM₁₀), metals such as lead and cadmium), and exposure to traffic-related pollution on ASD. The majority of recent studies have reported increases in risk of ASD with higher levels of estimated air pollution or proxies for it (such as distance to highways), though evidence regarding which specific component(s) of pollution are responsible for the observed association is far less consistent. In addition, recent studies have also started to explore modification of these effects by genetic variation.

The current epidemiological studies of HAPs and ASD have found moderately increased risk for ASD with industrial solvents. Maternal

prenatal exposure to chlorinated solvents and some heavy metals (mercury, lead, chromium, manganese, nickel) are associated with increased odds of ASD (Windham et al. 2006; Kalkbrenner et al. 2010; Roberts et al. 2013; von Ehrenstein et al. 2014; Talbott et al. 2015). These reports also implicate several toxicants as potential risk factors for ASD, but only few (styrene, solvents, diesel particulates, mercury, and lead) have been replicated. The most recent research on air toxins reported elevated associations with vehicular emission-related air toxins and industrial solvents (Kalkbrenner et al. 2018). Recent studies have used complex statistical techniques and adjusted for co-pollutants in analysis but utilize exposure assessment generated by the US National Air Toxics Assessment, limiting the spatial and temporal interpretability of results.

Most US-based studies that assessed PM_{2.5} have reported that the levels of fine particulate matter are associated with a moderate increase in the risk of ASD. Higher levels of PM₁₀, NO₂, and ozone are also implicated, but results are less consistent across studies. Within the CHARGE study, the presence of a genetic variant near the MET gene locus, coupled with high NO₂ exposure (Volk et al. 2014), increased the risk of ASD. In addition, increased copy number variation (CNV) burden, combined with elevated exposure to ozone, also resulted in much higher risk of ASD (Kim et al. 2017). Research using samples from other states have shown similar elevations in the risk for PM_{2.5}, and PM₁₀, ozone, and nitrogen oxides (Raz et al. 2015; Talbott et al. 2015). These studies used EPA air monitoring data-based dispersion models, traffic density, distance to roadways, and estimates based on residential history as well as land-use regression models.

In contrast to US-based studies, the evidence is more limited from other countries. A recent twin study that assessed nitrogen oxides and PM₁₀ based on road traffic estimated dispersion modeling did not find any significant associations with ASD (Gong et al. 2014). Similarly, one large study based on four European cohorts that measured these toxicants and PM_{2.5} based on land-use regression models (Guxens et al. 2016) also found no significant association with autistic traits.

A recent study in Israel that assessed NO₂ based on an optimized dispersion model found increased ASD risk for postnatal exposure but decreased risk for early prenatal exposure (Raz et al. 2018). The variation between US and international studies may stem from differences in outcome assessment, residual confounding in the US due to social factors, and the different mixtures of pollutants between nations. A recent review and commentary concluded that though there was potential for residual and unmeasured confounding in studies of air pollution and ASD, the likelihood of a true increase in risk associated with this factor was strong (Weisskopf et al. 2015). However, the focus of this discussion was primarily on confounding factors that tend not to change much over time intervals when air pollution changes. Further investigation of confounding is warranted.

Researchers have suggested that immune activation, neuroinflammation, and oxidative stress could be potential pathways for air pollution and its components to affect the developing brain and ultimately impact ASD risk. Although there is explosive growth in the quantity and quality of air pollution-related research, further work is needed. Future epidemiological studies need to consider exposure measurement limitations and residual confounding from SES, and factors that may vary in concert with air pollution including meteorologic and other variables develop methods to model pollutant mixtures, and identify critical windows of exposure relevant to the outcome, as well as further consider potential genetic interactions.

Pesticides

The toxic effects to the human body from acute pesticide exposures are well known, and work has also demonstrated adverse effects on neurodevelopment. Prenatal exposure to organophosphate pesticides (OP), a class of insecticides with wide-ranging agricultural uses, has been associated with abnormal reflexes (Engel et al. 2007), poorer mental development (Eskenazi et al. 2007) and a range of behavioral, cognitive, and neurologic deficits across many cohorts and study populations (Munoz-Quezada et al. 2013;

Gonzalez-Alzaga et al. 2014; Rauh et al. 2015). These exposures can be measured as individual metabolites in maternal biosamples, or through residential proximity to agricultural areas, which has been validated using air monitoring of pesticide applications (Wofford et al. 2014). A recent study used both exposure sources to assess associations with ASD traits and found that only prenatal urine total dialkyl phosphates (an OP metabolite) were associated with an increase in ASD traits as measured by the SRS (Sagiv et al. 2018). However, two other studies showed no associations with total OP metabolites and SRS scores (Furlong et al. 2014; Millenson et al. 2017). Only a few studies have examined associations with clinically diagnosed ASD: one, using prenatal measurements of OP metabolites, found no statistically significant associations in a very small study reporting preliminary findings (Philippat et al. 2018), although nonsignificant sex differences, with a higher risk among girls, but not boys, were noted. The first study to examine ASD in association with OPs and other agricultural pesticides using residential proximity reported significantly elevated odds of ASD associated with exposures in the top quartile for bifenthrin, a pyrethroid pesticide, and organophosphates (Roberts et al. 2007). Another study using proximity to agricultural pesticide applications found elevated risk for ASD, which was clinically confirmed by standardized diagnostic instruments. A significantly elevated risk was also noted for third trimester exposure to pyrethroids and second-trimester exposure to chlorpyrifos, the most commonly used agricultural OP pesticide (Shelton et al. 2014). Chlorpyrifos has been banned of neurodevelopmental harm, and recently the U.S. EPA proposed to revoke tolerances for residues in food, which would amount to a ban on agricultural uses, but subsequently reversed its position and announced there would be no such cancellation. In August 2018, EPA was ordered to finalize the ban by a U.S. Circuit Court of Appeals. In the meantime, chlorpyrifos is still being used in agriculture. Moreover, a recent study reported an interaction between exposure to these pesticides in pregnancy and folic acid, with the OP-related increased risk confined to those having low folic

acid intake (Schmidt et al. 2017); this interaction suggests that high folic acid may protect against the neurodevelopmental toxicity of pesticides, though replication of the finding is needed.

Another class of pesticides, organochlorines (OC), has also been examined in association with ASD. In the Roberts et al study based on residential proximity to agricultural pesticides (mentioned above), several OC pesticides were significantly associated with ASD (Roberts et al. 2007). In two studies using prenatal biomarkers of OC pesticides, results have been conflicting. Maternal prenatal serum concentration of one OC pesticide, trans-nonachlor, was associated with more ASD symptoms in a Cincinnati-based cohort study (Braun et al. 2014b), but a California-based study examining risk of diagnosed ASD (Lyll et al. 2017) found no association.

Considering that toxicity of pesticides has been known for a long time, surprisingly few studies have evaluated this exposure with ASD. Additional research is needed to clarify and replicate existing results and should consider the potential for exposure misclassification due to short half-lives of some OP pesticide metabolites, use sensitive and objective exposure measurement proxies, continue to explore time windows of sensitivity, and consider the potential effect modification of pesticides from other environmental and genetic factors.

Endocrine-Disrupting Chemicals

Endocrine-disrupting chemicals (EDCs) represent a class of substances (both persistent and nonpersistent chemicals) that interfere with the human endocrine system. Though some of these chemicals especially persistent EDCs are banned or have regulated use, the persistent nature of certain classes means that exposure is still relevant. As they are ubiquitously present in the environment, these substances have been studied for their effects on multiple neurodevelopmental outcomes over the last two decades.

OC pesticides, described above, are also known for their endocrine disrupting properties. Other EDC compounds examined in association with ASD include polychlorinated biphenyls

(PCBs), polybrominated diphenyl ethers (PBDEs), phthalates and bisphenol A (BPA). Two US and two international studies have evaluated the risk of ASD or measures of ASD symptoms in association with prenatal exposure to PCBs, but findings are contradictory. In a small pilot study, the sum of PCBs evaluated (Cheslack-Postava et al. 2013) was associated with an increased risk of ASD. Another study that measured 24 PCBs along with other EDCs in maternal blood reported inverse association with PCB-178 and SRS scores (Braun et al. 2014b). A German cohort study that summarized PCB congeners using the World Health Organization's defined toxic equivalency factors reported that PCB levels were associated with lower autistic mannerisms in their overall sample, and specifically among girls (Nowack et al. 2015). The most recent report measuring PCBs in second-trimester serum samples reported elevated risk of ASD with two congeners (PCB 153 and PCB 138/158) (Lyll et al. 2017), but further clarification of the role of PCBs in ASD is needed.

Though evidence links PBDE exposure to other adverse neurodevelopmental outcomes (Eskenazi et al. 2013; Chen et al. 2014), findings for ASD are limited. Only two studies have examined prenatal levels of PBDE in association with ASD, with conflicting findings. One study showed a marginally significant positive relationship with ASD symptoms as measured by the SRS (Braun et al. 2014b), and another found that elevated levels of certain PBDE congeners (PBDE-100, PBDE-153) were inversely associated with ASD diagnosis (Lyll et al. 2017; Traglia et al. 2017). In the latter study, there was also evidence of sexual dimorphism, with suggested, though not statistically significant, increases in risk with higher PBDE levels for girls and effects in the inverse direction for boys. It is possible that the inverse associations may be due to maternal and/or fetal genetic factors related to PBDE metabolism, as suggested in a follow-up to this study (Traglia et al. 2017).

The first study suggesting a link between phthalates and ASD was based on presence of PVC flooring in parents' bedroom (Larsson et al. 2009). However, in a study using measurements

of phthalates in household dust, no association was found with ASD, but associations were observed with several co-morbidities, including hyperactivity-impulsivity and inattention (Philippat et al. 2015). Only two studies have evaluated prenatal phthalate concentrations in biomarkers in association with ASD phenotype; one reported increased risk of SRS-measured ASD symptoms with increasing concentrations of low-molecular-weight phthalate metabolite concentrations in third-trimester urine (Miodovnik et al. 2011), and the other found no associations (Braun et al. 2014b). Few studies have examined BPA or perfluorinated compounds in association with ASD, and the results are inconsistent. Of note, phthalates and BPA are short-lived compounds, in comparison with PBDEs, PCBs, perfluorinated compounds and OC pesticides, all of which are persistent compounds with half-lives in the human body of months or years. Capturing exposures through the use of biologic markers is a greater challenge in the studies of compounds that are quickly excreted (phthalates, BPA, and the OP pesticides).

Other Environmental Chemicals

Like lead, methylmercury is a well-established neurotoxin with the primary source of human exposure through seafood consumption, but no associations with ASD have been described (van Wijngaarden et al. 2013; McKean et al. 2015). Several studies have suggested that mercury in air pollution is associated with an increased risk of ASD (Windham et al. 2006; Roberts et al. 2013; Lam et al. 2016). Although there are many reports on the differences in heavy metal levels between existing ASD cases and neurotypical controls, the primary hypothesis tested in these studies involves metabolic clearance of the toxicant rather than a causal mechanism of ASD (e.g., measurement of prenatal exposure), limiting interpretations. Innovations in this area, including the potential use of shed deciduous teeth or other novel biomatrices, may aid measurement of low-level prenatal exposures (Arora et al. 2017), but continued work is required.

Gene Environment Interactions

ASD is a complex neurodevelopmental condition, and evidence suggests significant environmental and genetic contributions to its etiology. However, because of the high degree of heterogeneity in both the environmental and genetic factors, it is possible that the combined effect of multiple genes and environmental factors contribute to the etiology over and beyond the main effects of individual genes or specific environmental factors. Over the last decade, there is a growing interest in evaluating gene-by-environment (GxE) interaction in ASD. Only a few studies have investigated GxE interaction in ASD to date. The first study reported significantly higher risk of ASD for children of mothers who did not take prenatal vitamins and had functional genetic variants involving inefficient conversion to folate or transmethylation in one-carbon metabolism (Schmidt et al. 2012). As mentioned before, mothers with the CC variant of the MET gene and high air pollution exposure had a higher risk of ASD compared to those with low pollution exposure and both CG and GG genotypes (Volk et al. 2014). Another study reported that children with ASD-associated CNVs and mothers with a history of infection during pregnancy had elevated ASD symptom severity compared to those without these factors (Mazina et al. 2015). CNV duplication and higher total CNV burden have also been shown to interact with ozone exposure in pregnancy until the second year of life to increase the risk of ASD (Kim et al. 2017). ASD-associated CNVs in children have been linked with other non-pollutant prenatal exogenous stressors as well. A recent study observed that exposure to first-trimester diagnostic ultrasound interacted with the presence of CNVs in autistic male children, increasing ASD symptom severity as compared to autistic male children with CNVs and no first-trimester ultrasound exposure (Webb et al. 2017).

Though of interest, the study of GxE in ASD is hampered by the need for both genetic and environmental data in the same study. In addition, as the potential mechanisms and possible interactions increase, large sample sizes are necessary to accurately estimate associations. Future research

harnessing collaborations across projects and linking datasets is expected to address these issues and expand the consideration of interactions in ASD (Hertz-Picciotto et al. 2018).

Conclusions and Future Directions

The complex and substantial heterogeneity in ASD phenotype and etiology makes studying suspected environmental factors challenging. Because ASD is a rare condition in the general population, few large-scale, prospective, population-based studies investigating environmental factors from preconception to diagnosis have been conducted. Replication of results for specific risk factors, clarification of mechanisms, and consideration of interactions are all key areas that studies of environmental risk factors for ASD will need to address in the future. However, considerable progress has been made in the past decade in our understanding of the role of the environment in ASD. This work has highlighted air pollution, parental age, the maternal intrauterine environment, various immune-related factors, and metabolic conditions as highly replicated risk factors for ASD and has provided suggestive findings warranting further consideration of other factors.

Several of the environmental risk factors discussed here are also associated with other adverse neurodevelopmental outcomes. Many substances cause multiple pathophysiological effects, and a better understanding of how common exposures can lead to diverse outcomes is needed. Though risk factors are often examined independently, exposures do not act in isolation. Considering the combined effects of multiple exposures, including not only GxE but also environment x environment interactions (to include nutrition) and exposure to complex chemical mixtures, may prove fruitful in gaining a better understanding of pathways. Additionally, incorporating objective biomarkers of exposure during biologically relevant time windows of neurodevelopment may serve this aim of clarifying mechanisms. Gold-standard biological measures of exposures, especially those that are not transient, could

supplement survey measures and improve the validity and precision of findings.

Another consideration for future work includes careful attention to timing. The prenatal period represents a key window of neurodevelopmental susceptibility, and some exposures may have even narrower windows of effect. Longitudinal pregnancy cohorts yield some of the richest sources of viable data, though these have been rare in ASD due to practical issues in assembling large enough study samples. One approach to mitigate this has been the use of high-risk pregnancy cohorts, which follow mothers who have already given birth to a child with ASD through a subsequent pregnancy (Newschaffer et al. 2012) – these studies have been critical in allowing for prospective investigation of a wide range of environmental risk factors for ASD and incorporation of biomarkers. However, sample sizes tend to be small, and the extent to which risk factors may differ in these families with perhaps increased genetic loading is unclear.

ASD clearly has a complex etiology, with multiple risk factors playing significant roles. Further investigations, using prospective design, large sample sizes, biological measures, and considering combined exposures, will be key to furthering our understanding of etiology and underlying mechanisms.

Epicanthic Fold

Abha R. Gupta

Developmental-Behavioral Pediatrics, Child Study Center, Yale University, New Haven, CT, USA

Synonyms

[Epicanthal fold](#); [Epicanthus](#); [Palpebronasal fold](#); [Plica palpebronasalis](#)

Definition

A skin fold of the upper eyelid that covers the inner corner (canthus) of the eye. It is seen normally in infants before the bridge of the nose develops and in East Asian people. It can also be a characteristic feature of some medical conditions, such as Down syndrome, fetal alcohol syndrome, Turner syndrome, Williams syndrome, and Noonan syndrome.

Epidemiology

Lisa Croen
Autism Research Program, Kaiser Permanente
Division of Research, Oakland, CA, USA

Definition

Epidemiology is a multidisciplinary field of study that focuses on describing, investigating, and preventing disease in populations. Studying diseases on the population level creates a level of complexity not seen on the individual level. In order to understand the movement and patterns of disease in a population, epidemiologists often need to be well versed in biology (disease transmission, symptoms, treatment), social sciences (population dynamics, behavior), statistics (analysis of population level data, visualizing trends and patterns), and rigorous scientific methods (study design, causal pathways). Epidemiology employs a scientific, evidence-based

approach to investigations of health and disease and thus is sometimes referred to as the scientific arm of public health.

Historical Background

The term “epidemiology” is of Greek origin and means “the study of what is upon the people.” One of the first epidemiologists was thought to be the Greek physician Hippocrates. Besides coining the terms “epidemic” and “endemic” in approximately 400 B.C., he also noted the association between yellow fever and malaria and swamps and advocated their drainage.

Several other notable epidemiologists included John Graunt (1620–1674), who was the first to use life tables to support and refute theories on certain diseases; James Lind (1716–1794), who used an experimental study design to determine that citrus could cure scurvy in sailors; and Ignaz Semmelweis (1818–1865), who cut maternal mortality rates by more than ninefold over a 6-year time period by requiring that physicians in his ward wash their hands with chlorinated lime between patient examinations (Merrill and Timmreck 2006).

Perhaps the most notable epidemiologist, though, is John Snow (1813–1858), whose breakthrough work on cholera in London helped develop modern epidemiology as it is known today. Snow gathered data on the incubation period of cholera and time from infection to death and even plotted mortality events on maps. Not only did he study the disease extensively, he also identified a potential cause of illness – contaminated water. He found that a brewery with its own water source was protected from cholera, while approximately 500 people died over a 10-day span within close proximity to the Broad Street water pump. This led to the famous removal of the Broad Street pump handle. Years later, John Snow conducted one of the first major epidemiologic studies in a randomized setting. Two companies were competing to supply water to individuals in London. The first company, Lambeth Water Company, took water from the Thames River from a relatively unpolluted upstream

source. The second company, Southwark and Vauxhall Water Company, drew water contaminated with the city's effluent. Both companies ran water pipes to the same areas, and thus citizens randomly chose one company or the other to obtain water (some citizens did not even recall which company they had chosen). Snow was able to obtain the addresses of those who died of cholera and then determine what water company supplied water to those households. In this way, he was able to demonstrate that water from the Lambeth Water Company was far safer than the fecally contaminated water provided by the Southwark and Vauxhall Water Company. This seminal work, conducted in the mid-1800s, was produced at a time when most physicians still believed in the same miasma, or bad air, that Hippocrates had believed in over 2,000 years prior (Snow 1855).

Since Snow's time, modern epidemiology has blossomed. In 1905, a school of tropical medicine was created at the University of London, and in 1916, Johns Hopkins University created the first school of public health. The Centers for Disease Control was created in 1946, and the National Institutes of Health was created soon after in 1948 Breslow and Cengage (2006). Several large epidemiologic studies were subsequently conducted that helped solidify the reputation of epidemiology as a rigorous science. One of the most definitive set of studies conducted in the later half of the twentieth century were those conducted by Doll and Hill (1950) and Hammond and Horn (1954) which established smoking as a strong risk factor for lung cancer.

The epidemiologic study of autism spectrum disorders (ASDs) began in 1943 with Kanner's first description of autism in 11 children. Since then, many hypotheses have been developed regarding the potential causes of autism. Early hypotheses suggested that cold detached parents were a cause of autism. In 1964, an epidemic of rubella infected both mothers and their unborn or newly born infants, causing 20,000–30,000 congenital malformations. In a study conducted by Stella Chess in 1971, out of 243 preschool children who had experienced congenital infection with rubella, ten were found to have autism

(as described by Kanner) and eight demonstrated some autistic behavior. This finding, along with others, began to suggest that autism could be a disease rooted in biology and not in parenting (Amaral et al. 2011).

Current Knowledge

The current practice of epidemiology employs a variety of study designs to accurately determine the relationship between exposures and health outcomes. The tools of epidemiology have been used to address a wide variety of research questions, ranging from genetic epidemiology to outbreak epidemiology, the epidemiology of aging, and the epidemiology of childhood developmental disorders such as autism.

Study designs can be categorized into one of two headings: experimental or observational. Experimental study designs include randomized controlled trials, or clinical trials, where participants follow well-defined protocols. These types of studies are quite powerful because perfect randomization allows investigators to examine only the causal effect of exposure on the outcome of interest and prevents other factors from influencing the relationship between the exposure and disease. These factors which influence both exposure and disease are often referred to as confounders, and presence of confounders may bias the relationship between exposure and disease. However, there are several limitations to the randomized controlled design. Studies like these seek to mimic laboratory type conditions, and more control requires more time and more resources. Thus, randomized designs are often quite expensive and difficult to conduct. In addition, many ethical issues can arise. For example, individuals with illnesses that might benefit from treatment cannot be expected to take placebos.

Observational studies include many designs; the most common being cohort studies, case-control studies, and cross-sectional studies. The goal of such observational studies is to determine the causal relationships between exposures and disease, though accomplishing this task with observational study designs is much more difficult

than with a randomized controlled trial due to potential confounding.

Case-control studies involve finding individuals who are diseased, cases, and then identifying a group of nondiseased individuals, controls, who come from the same population that generated the cases. The past exposure status for all study participants is then determined, and a relationship between exposure and disease can then be calculated. Case-control studies have the advantage of being much faster and cheaper to conduct than randomized trials or cohort studies. Case-control studies are especially effective when the disease of interest is rare. However, identifying an appropriate control population may be difficult. Another limitation is that unless all confounders are identified and accounted for, the relationship between exposure and disease cannot be described as causal. Thus, many case-control studies and observational studies in general report associations between exposure and disease, not causal relationships.

Cohort studies differ from case-control studies in that the opposite approach is taken. Rather than identify diseased and nondiseased individuals to begin with, cohort studies begin by identifying at-risk exposed and unexposed individuals. These nondiseased groups are then followed until the end of the study. Illness in the exposed and nonexposed groups is then compared. Cohort studies are often more expensive than case-control studies, but are much less expensive than randomized trials. Like case-control studies, they suffer from the limitation of potential unmeasured confounders. However, one critical advantage of cohort studies is that exposure is known to precede disease, a critical criteria for a causal relationship. In addition, investigators do not have to rely on study participants to remember prior exposure status, as in a case-control study.

Cross-sectional studies are similar to taking a picture of the population at one point in time. Information on exposure and disease is often collected at the same time, and temporal ordering may or may not be recorded. They differ from case-control studies in that cross-sectional studies often attempt to collect data on the entire population of interest. They are often even less expensive

to conduct than case-control studies. An example of a cross-sectional design is mailing a questionnaire to all employees of a company, inquiring about current exposure and health status. Another example involves use of census data to determine the relationship between an exposure and disease. However, one major limitation to cross-sectional studies that use “high-level” data such as census data is the ecological fallacy. The ecological fallacy exists when a relationship is seen at a population level that does not exist at the level of individual persons. An example of this is measuring the average IQ score for a population. While the average is appropriate to use at the population level, the IQ of any individual taken from that population could be higher or lower than the average. It would be a fallacy to assume that each individual had exactly the average IQ measured for the entire population.

All of the above study designs are subject to a variety of biases that can distort the relationship between the exposure and disease. One such bias is random error, which can arise when data tend to be randomly biased in one direction, and thus bias final results. A solution to this type of bias is to either measure variables more precisely in order to minimize random noise or to increase the number of participants or samples to the point where small random fluctuations are unlikely to alter the final results significantly.

Another type of bias is selection bias, which occurs when exposure or disease status influence participation in a study. For example, if researchers want to recruit children with ASD into a study, and advertise on TV and the Internet for participants, they may likely get a biased sample. More educated, financially well-off individuals may be more likely to see those advertisements and participate. Results from that study may differ greatly than a study conducted using a random sample from a comprehensive registry of children diagnosed with ASD.

Confounding is another bias and may arise when there are systematic differences between exposed and unexposed groups. These differences may lead investigators to falsely conclude that exposure alone caused differences in health outcomes. Confounders are typically factors that

cause exposure as well as disease. A simple example of this would be a study that investigated whether or not use of a mood-stabilizing medication among men with Asperger's syndrome could cause autism in their child. A naïve analysis examining the relationship between medication and the child's ASD status could find a strong association, but it is likely that much if not all of the associations could be explained by the genetic history of the father. Attributing all cases of ASD to the medication would be a biased conclusion, one that is often referred to as "confounded."

Another important source of bias is information bias. Information bias generally refers to the circumstance when data collected on an individual is not completely accurate. If a study participant reported having a relative with autism when that relative actually was diagnosed with obsessive compulsive disorder, that would be an example of information bias. Information bias is often broken into two categories: differential and nondifferential. Nondifferential bias refers to inaccurate measurement of either exposure or disease status, but the inaccuracy is the same in both the control and comparison groups. For instance, in a case-control study examining ASD as an outcome and maternal flu vaccination as an exposure, if mothers of children with ASD incorrectly reported their vaccination history in a similar fashion to mothers of children without ASD, then that "recall bias" would be referred to as nondifferential. However, if mothers of children without ASD underreported their flu vaccination history while mothers of children with ASD overreported their flu vaccination history, then that inaccurate measurement of exposure would be called differential (different recall in the case and comparison groups). Nondifferential misclassification is less concerning than differential misclassification. While both forms of bias typically give answers that differ from the truth, nondifferential misclassification gives answers that are biased consistently toward the null (no association), while differential misclassification can bias results either toward or away from the null. This unpredictability is undesirable and makes it difficult to interpret the results with any confidence.

Future Directions

Historically, epidemiology has been used to discover associations between exposures and disease. In fact, according to US law, epidemiology cannot be used by itself to prove causative relationships between exposure and disease in a particular individual; rather, it can only make a probabilistic statement about whether an exposure *could* have caused an outcome in an individual (National Research Council 2011). However, the science of epidemiology has always attempted to explore and identify causal relationships. With the advent of computers, developments in genetics, and availability of sophisticated measurement tools, epidemiologists have been able to better explore causal relationships between various exposures and diseases. Modern technology, including sophisticated statistical tools and electronic recording of data, has greatly improved the feasibility of conducting large, rigorous studies of health and analyzing large quantities of data. As the field of epidemiology continues to develop, there is great hope that previously untreatable diseases and health conditions will be better understood and that each successive generation will enjoy better health than those that came before.

biologist, geneticist, and philosopher who established foundations for systems biology. In 1942, predating knowledge of the physical nature of genes and their role in heredity, he used the term to refer to the study of the “causal mechanisms” by which “the genes of the genotype bring about phenotypic effects” (Waddington 1942). Early on, “epigenetics” was a vaguely understood idea that was often invoked to explain phenomena when basic genetic principles fell short. Despite an absence of direct scientific evidence, Holliday and Pugh (1975) and Riggs (1975) independently proposed the idea that *methylation* was a heritable epigenetic process that played an important role in regulating gene expression. Subsequently, a large amount of direct evidence accumulated which validated these ideas, and epigenetics began to evolve into a field of science whose molecular underpinnings were clarified. Holliday’s review of “the inheritance of epigenetic defects” (Holliday 1987) initiated widespread use of the term “epigenetic” during the 1990s. Today, molecular biologists define epigenetics as “the study of mitotically and/or meiotically heritable changes in gene function that cannot be explained by changes in DNA sequence” (Riggs 1996).

Epigenetic Mechanisms

Thomas Fernandez

Yale Child Study Center, Yale University School of Medicine, New Haven, CT, USA

Definition

Means by which gene expression is regulated without altering the underlying DNA sequence. Epigenetic mechanisms result in heritable annotations or modifications to DNA and associated histones which include the following: methylation, acetylation, ubiquitylation, phosphorylation, and sumoylation.

Historical Background

Coining of the term “epigenetics” is often attributed to Conrad H. Waddington, a developmental

Current Knowledge

Overview

Two predominant mechanisms provide the molecular basis for epigenetic regulation of gene expression: DNA methylation and histone modifications (which include methylation, acetylation, ubiquitylation, phosphorylation, and sumoylation of histone tails). These alterations are thought to alter the shape of chromatin, the complex of DNA wrapped around an octamer structure of histone proteins in the cell nucleus, and thereby affect gene transcription. Epigenetic mechanisms are active in both the germ line and somatic tissues; they are influenced by both genetic and environmental factors. The resulting epigenetic alterations can be conceptualized as comprising an “epigenotype” that is heritable between mother and daughter cells (meiotic inheritance) and between generations (mitotic inheritance).

Epigenetic modifications yielding differing epigenotypes are one explanation for how cells or organisms with otherwise identical DNA sequence may display different phenotypes. With regard to autism spectrum disorders (ASD), epigenetic modifications in several genes and genomic regions have been reported in both syndromic and nonsyndromic forms of ASD and may represent an important pathway in pathogenesis. Understanding the role of epigenetic changes in ASD is of particular interest, as their reversal may represent a potential target of novel therapeutic strategies.

DNA Methylation

Methylation is a well-characterized epigenetic modification that involves the covalent addition of a methyl group to cytosine bases at the carbon-5 position of a CG dinucleotide sequence of DNA (CpG dinucleotide) (Fig. 1). Regions of

the genome rich in CG dinucleotide sequence are known as CpG islands and exist in the promoter regions of approximately half of all known genes. Methylation occurs on both strands of a CpG dinucleotide via DNA methyltransferase (DNMT) enzymes and the methyl donor S-adenosyl-l-methionine (SAM). There is no known enzyme with DNA demethylating activity. Highly methylated regions are associated with a closed chromatin conformation state (heterochromatin), displaying less transcriptional activity and therefore less gene protein expression. DNA methylation may inhibit gene expression by direct interaction with factors that repress transcription, or indirectly through recruitment of methyl-CpG-binding proteins complexed with enzymes that modify histone proteins, transforming chromatin from an active to a repressed state. Alternatively, lack of methylation is associated with an open chromatin conformation state

Epigenetic Mechanisms, Fig. 1 *Epigenomic marks.* The epigenome can mark DNA in two ways, both of which play a role in turning genes off or on. The first occurs when certain chemical tags called methyl groups attach to the backbone of a DNA molecule. The second occurs when

a variety of chemical tags attach to the tails of histones, which are spool-like proteins that package DNA neatly into chromosomes. This action affects how tightly DNA is wound around the histones. (Courtesy of National Human Genome Research Institute)

(euchromatin), leading to more transcriptional activity and gene expression. Tumor growth has been associated with a state of hypomethylation, increasing the rate of mitotic recombinations from baseline and leading to genomic instability (e.g., structural rearrangements).

Histone Modifications

Another type of epigenetic mechanism which has the potential to modify gene expression involves chromatin remodeling via reversible covalent posttranslational modifications to histone proteins (Fig. 1). Two copies of four histone proteins (H2A, H2B, H3, and H4) form an octamer structure around which DNA is wrapped. The flexible N-terminus tails of histone proteins, H3 and H4, are most likely to carry numerous modifications of amino acids, including acetylation, methylation, phosphorylation, ubiquitylation, and sumoylation. Histone acetylation (via histone acetyltransferase enzymes) and phosphorylation is associated with an open or relaxed chromatin conformation state (euchromatin), facilitating transcriptional activity and gene protein expression. Conversely, histone deacetylation (via histone deacetylase enzymes) or sumoylation is associated with a closed or compact chromatin conformation state (heterochromatin), repressing transcription and gene protein expression. Other histone modifications may facilitate or repress transcription, depending on which amino acid residue is altered.

Epigenetic Syndromes and ASD

With respect to ASD, there are several examples of known epigenetic syndromes associated with increased risk. With the important caveat that intellectual disability in these syndromes may account for some of the observed phenotypic overlap in ASD, it is also possible that shared genes and epigenetic mechanisms may confer risk for ASD as well.

Rett Syndrome and Methyl-CpG-Binding Proteins

Many features of Rett syndrome (language impairments, stereotypic behaviors, seizures, sleep abnormalities, age of onset) are shared in common with autism, and both disorders are

classified as pervasive developmental disorders in DSM-IV-TR. Approximately 80% of Rett syndrome patients (almost exclusively females) and a small number of patients with autism (without Rett syndrome) have been reported with rare and common mutations in the *MECP2* gene on the X chromosome. This transcript codes for a methyl-CpG-binding protein with functional domains for methyl binding and transcription repression via inhibition of transcription factor binding; it may also facilitate histone modifications. Studies of *MECP2* in autism have shown decreased brain expression relative to matched controls, and expression levels have been correlated with rare variants and hypermethylation in the gene's promoter (Nagarajan et al. 2006).

Fragile X Syndrome

Fragile X syndrome (FXS) is linked to the expansion of a CGG repeat sequence in the 5' untranslated region of the *FMR1* gene on chromosome Xq27. These repeat expansions lead to increased methylation, decreased acetylation, and therefore decreased expression of *FMR1*, a gene whose protein product is involved with RNA processing. Such epigenetic modifications appear to be crucial to the development of FXS, as a normal phenotype in the presence of the CGG repeat allele is observed if hypermethylation is absent. ASD risk for full-mutation (>200 CGG repeats) males and females range from 60% to 67% and 10% to 23%, respectively, based on studies using the Autism Diagnostic Interview (ADI) and Autism Diagnostic Observation Schedule (ADOS) (Clifford et al. 2007). Shared ASD features include repetitive behaviors, language impairments, and eye-gaze aversion.

Prader-Willi and Angelman Syndromes

Both Prader-Willi syndrome (PWS) and Angelman syndrome (AS) have an increased risk for ASD (19–37% for PWS and 42–100% for AS) (Hogart et al. 2010). These syndromes result from a specialized epigenetic mechanism called imprinting, a phenomenon by which each parent contributes different “epigenotypes” via their germ cells for specific genomic loci. DNA methylation or histone acetylation marks one

allele of an imprinted gene and prevents its transcription/expression. This yields monoallelic expression of an imprinted gene. PWS and AS are caused by epigenetic errors or chromosomal rearrangements at an imprinting cluster on chromosome 15q11-13 (e.g., AS results from loss of *UBE3A* expression, a gene that is normally expressed exclusively from the maternal chromosome) (Nicholls and Knepper 2001). Increased risk for ASD in PWS and AS and an increased risk for ASD with maternal duplications of 15q11-13 (with and without PWS and AS) suggest that a loss of imprinting may increase susceptibility to ASD (Veltman et al. 2005).

Epigenetic Modifications in ASD Candidate Genes

In addition to one report of ASD association with increased *MECP2* methylation, as mentioned above, there is some evidence that other (nonimprinted) ASD candidate genes may be epigenetically regulated. One study found increased DNA methylation in the promoter of the oxytocin receptor gene (*OXTR*) in blood and temporal cortex (Gregory et al. 2009). Similarly, the long allele of the reelin gene (*RELN*) has been associated with ASD and appears to cause decreased gene expression via epigenetic mechanisms (Persico et al. 2006). Serotonin transporter genes and *BDNF* (*brain-derived neurotrophic factor*) are included among other candidate genes which are being investigated for evidence of epigenetic regulation (Rumajogee et al. 2002). While these genes have not been definitively demonstrated to play a role in ASD, they are one line of evidence that epigenetic mechanisms could contribute ASD pathogenesis.

Environmental Influences on Epigenetic Modifications

There is some evidence that certain environmental exposures may cause epigenetic changes which can lead to increased risk for ASD. One example is prenatal exposure to valproate. The risk of ASD to children of mothers taking this drug during pregnancy has been estimated up to

15 times the general population risk (Rasalam et al. 2005). Two possible mechanisms of valproate teratogenicity include interference with folate metabolism, which can modify gene expression in certain metabolic pathways, and inhibition of histone deacetylases, which can result in increased expression of multiple genes (Phiel et al. 2001). Furthermore, decreased expression of an autism candidate gene, *NLGN3*, has been reported in mice treated with valproate (Kolozsi et al. 2009).

Future Directions

Epigenetic mechanisms that regulate gene expression have emerged as a fundamental mechanism in developmental biology and the pathogenesis of disease. New technologies allowing high-throughput and whole-genome screening for DNA methylation and chromatin modifications hold great promise for the identification of epigenetic determinants in ASD. Given that epigenetic modifications to DNA are potentially influenced by environmental factors, elucidating the epigenetics of ASD could lead to the development of a new era of therapeutics.

Seizure disorder

Short Description or Definition

Epilepsy is operationally defined as more than one unprovoked seizure of any type. Recent definitions of epilepsy have emphasized the neurologic, cognitive, psychological, and social consequences of this group of disorders (Fisher et al. 2005). Epilepsy, like autism, is not one disorder and is best conceptualized as the epilepsies.

Seizures are clinical events characterized by paroxysmal, stereotyped, relatively brief interruptions of ongoing behavior, associated with electrographic seizure patterns (ILAE 1981). The term “subclinical or nonconvulsive seizure” is used to refer to electrographic patterns without clinically recognizable cognitive, behavioral, or motor functions or apparent impairment of consciousness and requires concurrent electroencephalogram (EEG) during behavioral testing. Seizures are differentiated into those that are provoked secondary to an acute event such as fever, infection, trauma, or metabolic illness and those that are unprovoked (i.e., seizures that are likely to be genetic). There are *two peaksof seizureonset* in autism. The early peak of seizure onset in autism occurs in the first 5 years of life and is commonly associated with epileptic encephalopathies (see below). The second peak of seizure onset starts in adolescence and continues into adulthood. This secondary peak of seizure onset may be more

common in individuals with ASD than early onset seizures and as such may represent a different distribution of seizure onset than in the general population (Bolton et al. 2011).

Interictal epileptiform discharges and epileptiform activity are terms used interchangeably to describe abnormal electroencephalogram (EEG) activity, specifically referring to spikes alone or accompanied by a slow wave, occurring either singly or in bursts and lasting at most 1 or 2 s. The association of epileptiform activity with an epileptic disorder is variable. The term “subclinical or nonconvulsive seizure” has also been used to refer to electrographic patterns without clinically recognizable cognitive, behavioral, or motor functions or any apparent impairment of consciousness. Studies on the prevalence of epileptiform activity in individuals with ASD and no clinical history of seizures range from 6% to 31% (Kagan-Kushnir et al. 2005). There is significant controversy regarding the specificity of these findings to the ASD phenotype, and it is likely that the high prevalence of epileptiform activity in ASD is secondary to pathophysiological processes common to autism and other neurodevelopmental disorders. The treatment of interictal epileptiform discharges in children with autism remains controversial with little evidence that suppression of spikes accounts for behavioral improvement, except in rare clinical scenarios (see below under epileptic encephalopathies) (Tuchman et al. 2010).

Epidemiology

The prevalence of epilepsy in ASD is highly variable and depends on the cohort studied, with rates ranging from 5% to 46% (Spence and Schneider 2009). The reported rates of epilepsy in ASD are several fold higher than the 0.5–1% prevalence of epilepsy in the general population but are similar to the prevalence of epilepsy in a population of children with intellectual disability, with the highest rates of epilepsy in those with severe cognitive impairments (Tuchman et al. 2010).

Natural History, Prognostic Factors, and Outcomes

A consistent finding across multiple studies of autism and epilepsy is that severity of intellectual disability is a significant risk factor for the development of epilepsy in children with ASD (Amiet et al. 2008). Individuals with ASD and epilepsy are, as a group, significantly impaired as young adults (Danielsson et al. 2005), and children with autism and epilepsy have worse cognitive (lower IQ), adaptive, behavioral, and social outcomes than children with autism without epilepsy (Hara 2007; Turk et al. 2009).

Clinical Expression and Pathophysiology

Clinical Expression

Epilepsy syndromes are differentiated based on clinical findings, etiology, and patterns of EEG abnormalities. The most common epilepsy syndromes associated with autism spectrum disorders, especially those in which the epilepsy begins in the first 3 years of life, are the *epileptic encephalopathies*.

Epileptic encephalopathy is defined as “a condition in which the epileptiform abnormalities themselves are believed to contribute to the progressive disturbance in cerebral function” (Berg et al. 2010; Engel 2001). As a group, the epileptic encephalopathies are associated with regression or slowing of cognitive, language, or behavioral development; the hypothesis is that the seizures or the interictal epileptiform activity are responsible for the deterioration (Dulac 2001; Nabbout and Dulac 2003, 2008). Among these epileptic encephalopathies, *West syndrome* or *infantile spasms (IS)*, *Landau-Kleffner syndrome (LKS)*, and *epilepsy with continuous spikewaves during slow-wave sleep (CSWS)* are most commonly associated with an ASD phenotype (Ballaban-Gil and Tuchman 2000). However, it should be noted that the ASD phenotype might not be exclusive to these three encephalopathies; the ASD phenotype may be under-recognized or under-investigated in other epileptic encephalopathies such as *Dravet syndrome* (Wolff et al. 2006).

Infantile spasms are associated with multiple etiologies and represent a distinct subgroup of epilepsies with poor cognitive and social outcomes. Infantile spasms is an age-specific epilepsy syndrome that occurs between 3 and 18 months with a peak age of presentation between 4 and 8 months of age (Zupanc 2009). The seizure consists of a sudden flexion or extension of the proximal and truncal muscles which lasts for approximately 0.2–2 s. They are more prolonged than a myoclonic jerk (<100 ms) but less sustained than a tonic seizure (few seconds to minutes). Frequently, they are associated with high-voltage abnormalities on the interictal EEG that have been called hypsarrhythmia. Coincident intellectual retardation or regression of neurodevelopment in infantile spasms is common. The risk of developing autism after having infantile spasms is approximately 46% but can be as high as 69% in those with infantile spasms and significant associated brain lesions.

Dravet syndrome is a genetically determined infantile epileptic encephalopathy mainly caused by de novo mutations in the *SCN1A* gene (Scheffer et al. 2009). Progressive decline or plateau in development occurs by 1–4 years of age with intellectual disability and an autism phenotype commonly present especially in those with greater than five seizures per month (Wolff et al. 2006). There is emerging evidence that vaccine encephalopathy, characterized by the appearance of seizures and regression in infants following vaccination, may be secondary to SCNA1 gene mutations in these infants, suggesting that vaccine encephalopathy could, in fact, be a genetically determined epileptic encephalopathy (Berkovic et al. 2006).

A controversial example of an epileptic encephalopathy that has been linked to ASD is *Landau-Kleffner syndrome (LKS)*, an acquired aphasia in association with an epileptiform EEG with spikes, sharp waves, or spike and wave discharges that are usually bilateral and occur predominantly over the temporal regions (Landau and Kleffner 1998). On a continuum with Landau-Kleffner syndrome is *continuous spike waves during slow-wave sleep (CSWS)*, an epileptic encephalopathy associated with the

EEG pattern of *electrical status epilepticus during slow-wave sleep (ESES)*, various seizure types, and cognitive, motor, and behavioral disturbances (Tassinari et al. 2009). Continuous spike waves during slow-wave sleep and Landau-Kleffner syndrome are *sleep-related epileptic encephalopathies* with common clinical features including seizures, regression, and epileptiform abnormalities that are activated by sleep (Nickels and Wirrell 2008). In continuous spike waves during slow-wave sleep, there is a regression in global skills, while in Landau-Kleffner syndrome, the primary clinical manifestation is a regression of language. *Autistic regression with an epileptiform EEG* is the terminology used to describe the association of an epileptiform EEG in children with autistic regression, e.g., those in whom both language and social skills are lost. This group of children should be differentiated from those with LKS. In this group of children, the language and social skill loss occurs earlier, before the age of 2, as compared to those with LKS in which it occurs usually after age 3 years. In addition, the children with autistic regression and an epileptiform EEG usually do not have frequent spikes on the EEG and rarely have the ESES EEG pattern common in LKS. The importance of differentiating children with autism, regression in language and social skills, and epileptiform EEG from those with LKS is that there is no evidence that the treatments used in LKS, such as the use of steroids or surgical interventions, are effective interventions for this group of children (Tuchman 2009).

Pathophysiology

The word “epileptogenesis” in pediatrics refers to dynamic processes which constitute the appearance and natural history of epilepsy. The appearance of autism in epilepsy patients and epilepsy in autism patients suggests that a final common set of neural pathways and molecular processes are shared by both autism patients and epilepsy patients. The understanding of the development of epilepsy, progression of epilepsy, and interaction between epileptic seizures and cerebral maturation will be critical to our knowledge of epileptogenesis in autism epilepsy patients.

Mechanisms responsible for epileptogenesis of partial seizures may be shared among autism and nonautism patients. Models of partial epilepsy reveal a characteristic course in the development of isolated epileptogenic lesions (Thom et al. 2010). Children under 10–11 years of age tend to have epileptiform discharges focally in the centrottemporal or centroparietal regions (Chez et al. 2006). Thus, mechanisms responsible for focal epilepsy may be applicable to younger children with autism/epilepsy. First, a localized structural or molecular change occurs in the region of brain tissue which in itself may not cause seizures. Reorganization of synaptic inputs with altered neural integration ensues, which, in many cases, change the regional balance to excessive excitation and pathologic synchronization of action potential firing. Localized interictal EEG spikes occur in this region, and later, in most cases, spontaneous seizures are seen emanating from the site.

The *kindling model of epilepsy* demonstrates the process of partial epileptogenesis. Kindling is a process by which initially subconvulsive electrical stimulus to a brain region, such as the amygdala, is repeated once a day for 21 days. An initial subconvulsive electrical stimulus may only evoke an electrographic discharge with little change in the animal's behavior (Racine et al. 1975). The repeated electrical stimulus will evoke first a behavior arrest (class I seizure) and then stepwise at day 21 evoke a secondarily generalized tonic-clonic seizure (class V seizure). An animal is considered fully kindled when the same stimulus evokes a secondarily generalized tonic-clonic seizure over three consecutive days. Electrophysiologic and structural analyses of kindled animals suggest permanent alterations to rodent limbic cortex which parallels changes seen in human temporal lobe epilepsy (Morrell and de Toledo-Morrell 1999). The genetic program activated over a period of time includes three phases: (1) expression of immediate early genes and apoptosis genes, (2) expression of secondary transcriptional regulatory proteins, and (3) expression of tertiary or quaternary target genes (neurotrophins, guidance cue genes, etc.) in response to transcriptional regulatory proteins

and electrical activity. The end result of this genetic reprogramming is synaptic reorganization and epileptogenesis. The final common pathway here seems to be recurrent excitatory networks. Kindling causes epileptogenesis by a variety of possible mechanisms including (1) reorganization of axons/synaptic connections, (2) alterations in AMPA and NMDA receptors, (3) enhanced release of glutamate by neurosecretory mechanisms, and (4) alteration of inhibition via kainic acid receptor activation (Wang et al. 2010).

Shared Molecular Pathophysiology Between Autism and Epilepsy

Genetic Components

The standard hypothesis to explain the overlap of autism and epilepsy is that an altered balance between excitation and inhibition is one biological mechanism for both diseases; thus, the disturbance in the development of either cortical projection neurons or interneuron maturation would tip over this delicate balance. Giving the fact that autism co-occurs with numerous neurodevelopmental disorders and the complexity of synaptogenesis and function, it is not surprising that there are multiple molecules and signaling pathways associated with the pathogenesis of autism. Subtle perturbations or alterations in any of these molecules critical in neurodevelopment, synaptogenesis, and synaptic function may cause defects in the downstream common biological pathways within brain circuits contributing to ASD pathogenesis (Geschwind and Levitt 2007).

The genetic architecture of autism includes at least two distinct genetic mechanisms: rare, private (de novo) single-gene mutations that may have a large effect in causing ASD and inherited, common functional variants of a combination of genes, each having a small to moderate effect in increasing ASD risk (Abrahams and Geschwind 2008; O'Roak and State 2008; Veenstra-VanderWeele and Cook 2004; Weiss et al. 2009). Rare point mutations range from ASD risk genes encoding numerous synaptic proteins (such as contactin-associated protein-like 2, CNTNAP2; SH3 and multiple ankyrin repeat domains 3, SHANK3; and neuroligin-3, NLGN3) to gains

or losses of DNA segments, termed copy number variation (e.g., 16p11.2 and 15q11-q13), and to gross chromosomal rearrangements that are estimated to occur in about 7% of autism cases (Abrahams and Geschwind 2008).

In epilepsy, genetic advances have identified ion channel genes as the major category of epilepsy susceptibility genes, although nonion channel genes have also been identified to be associated with epilepsy (Suzuki et al. 2004). These ion channels include both voltage-gated and ligand-gated ion channels. The voltage-gated ion channels include sodium channels like SCN1A, SCN2A, and SCN1B; potassium channels like KCNQ2 and KCNQ3; and calcium channels like CACNA1A (Glasscock et al. 2007) and CACNB4 (Escayg et al. 2000). The ligand-gated ion channels include GABA_A receptors (Kang and Macdonald 2009) and nicotinic acetylcholine receptors (Steinlein and Bertrand 2010). Mutations of these ion channel genes that either directly or indirectly enhance excitatory neurotransmission or reduce inhibitory neurotransmission increase brain hyperexcitability and thereby predispose patients to seizures. Rare copy number variations, already implicated in ASD (Weiss 2009), have been noted in patients with idiopathic generalized epilepsy (IGE) (Carmona-Mora and Walz 2010; Sisodiya and Mefford 2011). IGEs are a well-defined group of epilepsies, accounting for a third of all cases of epilepsy in the general population and an even higher proportion in children (1). IGEs usually begin in childhood, are genetically determined, and have no structural or anatomic cause (Benbadis 2005). However, the prevalence of this genetic mechanism in IGEs remains to be established.

There are a number of mutations or variants in GABA_A receptors that have been associated with epilepsies of various phenotypes (Kang and Macdonald 2009; Macdonald et al. 2010). These mutations/variants associated with epilepsies have been reported in $\alpha 1$, $\beta 3$, $\gamma 2$, and δ subunits. Most of the mutations have autosomal dominant inheritance and have been associated with epilepsy syndromes comprised of pure febrile

seizures (FS), mixed afebrile and febrile seizures such as CAE and FS, generalized epilepsy with febrile seizures plus (GEFS+) syndrome, Dravet syndrome, and juvenile myoclonic epilepsy (JME). These mutations include missense, nonsense, and intronic splice donor site mutations. Most of the mutations are associated with fairly mild phenotypes like simple febrile seizures and CAE which are outgrown with age. In summary, defects in multiple genes and molecules may lead to alterations in the final common neural pathways involved in the pathogenesis of epilepsy and autism. Among all these genetic and molecular pathways, impaired GABAergic signaling is a prominent pathology underlying the pathogenesis of both autism and epilepsy.

Abnormal Brain Development

Both autism and epilepsy have abnormal brain development. But there are many more studies on brain development of autism than on epilepsy. Cross-sectional magnetic resonance imaging (MRI) studies have long hypothesized that the brain in children with autism undergoes an abnormal growth trajectory that includes a period of early overgrowth. The abnormalities in autism could be broad including frontal and temporal lobes, amygdala, basal ganglia, corpus callosum, parietal lobe, and cerebellum (Allen and Courchesne 2003). In addition to the identification of brain overgrowth in autistic brains (Courchesne 2002; Courchesne et al. 2003), Courchesne and his group also demonstrated the first direct evidence with MRI study that anatomic abnormalities within the limbic system exist from the earliest years of autism and change throughout development and up through middle age. It is worth noting that cerebellar abnormality is repeatedly reported in most specimens examined, thus challenging the view that the function of cerebellum is exclusively motor coordination (Allen and Courchesne 2003). Interestingly, gene mutations in GABRA6 (Dibbens et al. 2009) were also associated with epilepsy. The transcript of $\alpha 6$ subunit was reported to be confined to the postnatal

cerebellum (Laurie et al. 1992). This may suggest that this subunit may exist in other unknown brain areas or argue against the role of cerebellum simply being motor coordination.

There are shared neuropathologies underlying ASD and epilepsy (Taylor et al. 1999; Wegiel et al. 2010). SPECT/PET scans of autism/epilepsy patients and pediatric patients with medication-resistant focal epilepsy caused by focal cortical dysplasia show similar areas of abnormalities in the frontal or temporal cortex (Sasaki et al. 2010). The discrete focal areas of hypometabolism suggest similar cellular abnormalities in the cortices of both types of patients (Sasaki et al. 2010; Taylor et al. 1999; Wegiel et al. 2010). The initial overgrowth in autism patients is associated with focal developmental abnormalities. The focal abnormalities include subependymal nodular dysplasias, subcortical and periventricular heterotopias, dysplasias including either cell loss or increased numbers of poorly differentiated neurons with disturbed lamination in neocortex, archicortex, dentate gyrus, cornu ammonis, and cerebellar cortex (Taylor et al. 1999; Wegiel et al. 2010). In autism brain, tuber-like structures as seen in tuberous sclerosis are detected in cortical and subcortical regions such as the basal ganglia (Numis et al. 2011). Older autopsy specimens tend to be associated with cell loss and disturbed cortical minicolumns. Posterior regions of the corpus callosum are also reduced in size in autism in a study of 3- to 42-year-olds (Schumann et al. 2010). MRI studies of older ASD children suggested that altered volumes of caudate nuclei, hippocampi, amygdale, and corpus callosum are associated with higher rates of epilepsy and lower sensory response rates (Bloss and Courchesne 2007; Brambilla et al. 2003; Schumann et al. 2004, 2010). In conclusion, these recent MRI and neuropathology observations suggest abnormal regulation of brain growth in autism: overgrowth early in life followed by abnormally slowed growth in some regions, but premature arrest of growth/poor differentiation followed by cell loss in others.

The role of pathologic neural activity such as interictal epileptiform discharges (IEDs) and

seizures in the developing brain of children with ASD is less clear. Evidence from human epilepsy and ASD patients indicates that there is abnormal and equivalent histology in human mesial temporal sclerosis and ASD hippocampi (Blumcke et al. 2009). These changes include substantial granule cell loss and architectural abnormalities like granule cell dispersion, ectopic neurons or clusters of neurons in the molecular layer, or bi-lamination (Blumcke et al. 2009). However, the contribution of abnormal brain development and neural activity in IGEs has just started to draw attention. For example, the knock-in mice harboring GABRG2 (R43Q) is a mutation associated with febrile seizures and childhood absence epilepsy. Activation of the mutant allele GABRG2 (R43Q) during early development increased the seizure susceptibility, and inactivation of the mutant allele would decrease the seizure susceptibility. These data suggest that disruption of the physiological effects of GABA_A receptors during the sensitive developmental epochs in fetal and neonatal/infantile life may compromise the developmental processes that are crucial for normal brain development and facilitate the development of epilepsy (Chiu et al. 2008). This may underlie why patients carrying GABA_A receptor subunit mutations have mental compromise ranging from mild learning difficulty to mental retardation in addition to seizures and autism such as those seen in Dravet syndrome (Li et al. 2011).

Abnormal GABA Receptor and Excitatory Receptors in Autism

The balance of excitatory and GABA neurotransmission throughout brain development determines the final trajectory of neural pathways responsible for cognitive and behavioral output in autism and epilepsy patients. Although it is unknown of how exactly GABA_A receptor function affects neurodevelopment, a recent study demonstrated that activation of GABA_A receptors leads to hyperpolarization, increased cell volume, and accumulation of stem cells in S phase, thereby causing a rapid decrease in cell proliferation (Andang et al. 2008). Any subtle change in stem cells may have profound impact

in neuronal function and leave imprint on later brain network activity. In addition to altered interneuron and excitatory neuronal numbers, studies on brain specimen of both autism and epilepsy from multiple investigators have consistently demonstrated that the expression of GABA_A receptors and ionotropic glutamate receptors is altered in both disorders (Fatemi et al. 2010; Jansen et al. 2010).

In the case of GABA, the alterations extend to multiple GABA_A receptor subunits instead of single GABA_A receptor subunit. This aberrant profile of GABA_A receptors is consistent with the complex GABA_A receptor assembly and dynamic expression patterns in the brain. In normal brain, expression of GABA_A receptor subunits varies regionally and temporally. For example, $\alpha 1$ and $\alpha 2$ subunits have low expression in early brain but increase over development and then stabilize through adolescence and adulthood, whereas $\alpha 4$ subunit expression is higher in infants than in older children. But based on a recent study in epilepsy patient brains, the normal expression pattern of GABA_A receptor subunit is absent in those with focal cortical dysplasia and in those with gliosis (Jansen et al. 2010). Brain specimens of autism patients have demonstrated that systematic changes in GABA_A subunit expression (Fatemi et al. 2010; Fatemi et al. 2009). Oblak demonstrated reduction of GABA_A receptors and benzodiazepine binding sites in both the anterior and posterior cingulate cortices and fusiform gyrus in autism (Oblak et al. 2009, 2011). Given the fact that GABA_A receptor traffics and functions as pentamer at the cell surface and synapse and the receptor stoichiometry of $2\alpha(x)2\beta(x)1\gamma$, $2\alpha(x)2\beta(x)1\delta$ or $2\alpha(x)3\beta(x)/3\alpha(x)2\beta(x)$, it is not surprising that multiple GABA_A receptor subunits are reduced. The brain regions that displayed different distribution include superior frontal cortex, parietal cortex, and cerebellum of subjects with autism (Fatemi et al. 2009, 2010). The fact that multiple regions are affected suggests the comprehensiveness of neurodevelopment abnormalities. There are also multiple mechanisms underlying the GABA_A receptor subunit protein reduction: (1) altered GABA_A receptor mRNA levels or stability, (2) altered posttranslational modifications

which reduce subunit maturation and receptor forward trafficking, (3) reduced neuronal numbers due to cell death of presynaptic interneurons, and (4) altered epigenetic regulations of GABA_A receptor subunits (Samaco et al. 2005).

Further research is needed to more fully understand how glutamate receptor and transporter biology is affected in autism and how it may contribute to epilepsy as a comorbidity in ASD. The core features of autistic brain development suggest that alterations of excitatory neuronal numbers may, in themselves, account for changes in excitatory receptor concentrations. In addition to abnormal minicolumnar structure in the frontal, temporal, and anterior cingulate cortices, Courchesne et al. (2011) recently reported that neuronal counts in the dorsolateral prefrontal cortex and the medial prefrontal cortex in autistic brains were increased by 79% and 29%, respectively, compared to similar young age-matched males (Casanova 2006). The idea of increased proliferation or reduced apoptosis in autistic brains leading to excessive production of excitatory neurons may explain the increases in many axonal tracts of autistic brains and increased local functional connectivity (Allen and Courchesne 2003). Studies of the blood have shown either increases or decreases in blood glutamate or blood glutamine (Lam et al. 2006). Gene expression studies have shown upregulation of several glutamate receptors or linked genes including EAAT1, GluR1, GluR2, and GluR3 mRNAs in the cerebellum and hippocampus of autistic individuals (Purcell et al. 2001). Surprisingly, few actual glutamate receptors or transporters are among identified ASD-associated genes including kainate receptor GluR6, metabotropic GluR8 (GRM8), NMDA receptor GRIN2A, and AMPA receptor-associated protein GRIP1 (Barnby et al. 2005; Choudhury et al. 2012; Mejias et al. 2011). Many of these associations are significant since these proteins control interneuron excitability (GluR6, GRIN2A), gamma oscillations from parvalbumin interneurons, critical periods (GRIN2A), and AMPA/GABA receptor expression (GRIP1 variants) in synapses (Endele et al. 2010; Fisahn et al. 2004; Kocsis 2011; Mejias et al. 2011; Zhang and Sun 2011).

Abnormal Neurotransmitter Signaling in Neurodevelopmental Disorders with Autism and Epilepsy as a Phenotype

Epilepsy and autism are comorbid in several neurodevelopmental disorders which, at their core, have impaired synaptic homeostasis. These disorders include, but are not limited to, Dravet syndrome, tuberous sclerosis, Angelman syndrome, fragile X syndrome, and Rett syndrome. GABA signaling could participate in neurodevelopmental disorders because GABA occupies a central role in development. Patients with these syndromes often suffer from autism, intellectual disabilities, and epilepsy. GABAergic function impairment may be a common pathway for many neurodevelopmental disorders including autism and epilepsy. It is not surprising given the essential role of GABA signaling in brain development. The exact mechanism of the concurrent epilepsy and autism in these neurodevelopmental disorders remains unclear. However, from both animal and genetic studies, altered GABAergic signaling is consistently observed in these disorders. In Angelman syndrome, a maternally inherited deletion of 15q11-13 locus is identified in the majority of cases. The deletion includes the UBE3A gene (ubiquitin-protein ligases E3A) as well as three GABA_A receptor subunit genes: the GABRB3, GABRA5, and GABRG3 (Hogart et al. 2007; Knoll et al. 1989; Wagstaff et al. 1991). UBE3A signaling controls EphB-EphrinB regulation of glutamate synapse development (Margolis et al. 2010). Conversely, increased dosage of UBE3A results in mice with autistic-like behavior and decreased glutamate neurotransmission (Smith et al. 2011).

In fragile X syndrome, GABA_A receptor subunits are downregulated, possibly due to lack of translational regulation by FMRP1 (D'Hulst et al. 2006; Fatemi et al. 2011). Studies on fragile X syndrome indicate that the increased activation of metabotropic glutamate receptor 5 (mGluR5), a member of the group I mGluR family, contributes to a predisposition for the development of epilepsy, autism, and other neuropsychiatric disorders (Bianchi et al. 2009). The major neuropsychiatric features of fragile X syndrome are caused by unchecked activation of mGluR5

(Bear et al. 2004), and downregulation of postsynaptic mGluR5 signaling can correct developmental disorders in the disease (Dolen et al. 2007). Depolarized firing states of neurons are driven by recurrent local excitation and inhibition in a given cortical region which underlies the so-called slow oscillation neocortical rhythm (<1 Hz). Aberrant postsynaptic mGluR5 signaling in neocortex of FXR1 KO mice alters this slow oscillation and inhibitory dendritic currents from somatostatin interneurons (Hays et al. 2011; Paluszkiwicz et al. 2011). Additionally, transient local hyperconnectivity of prefrontal cortex during development and abnormal presynaptic short-term plasticity contributes to slower synaptic responses and integration of informational processing in the FXR KO mice (Deng et al. 2011; Testa-Silva et al. 2011). All these mechanisms contribute to the aberrant maturation and function of synchronized cortical rhythmic activity needed for behavioral and cognitive output of neural networks.

In FXR KO mice, increased mTOR signaling and increased protein synthesis is associated with the above described synaptic pathology and seizures (Carson et al. 2012). In contrast, recent advances in TSC KO mouse studies show increased synaptic mTOR signaling, and *decreased* protein synthesis is associated with reductions in glutamate and GABA neurotransmission (Auerbach et al. 2011). In tuberous sclerosis (TSC), there is altered transcription of genes encoding glutamatergic and gamma-aminobutyric acid (GABA)-ergic receptors. GABRA1 and GABRA2 mRNA levels were reduced in both dysplastic neurons and giant cells compared to control neurons (White et al. 2001). In Rett syndrome, the recent study by Zoghbi et al. (2010) demonstrated that MeCP2 is critical for normal function of GABA-releasing neurons and that subtle dysfunction of GABAergic neurons alone can recapitulate the numerous neuropsychiatric phenotypes and epilepsy common to Rett syndrome patients (Chao et al. 2010). In addition to this comprehensive list of neurodevelopmental disorders, impaired GABAergic signaling is frequently identified in other ASD- and epilepsy-associated genes too. For example, genetic disruption of the autism spectrum disorder risk genes

MET, PLAUR, and neuropilin-2 induces the alteration of GABA_A receptor subunits and defects in GABAergic and excitatory circuitry which lead to autistic-like traits and epilepsy (Brooks-Kayal 2010; Eagleson et al. 2010; Gant et al. 2009; Powell et al. 2003).

In summary, the phenotypical and genomic heterogeneity of both autism and epilepsy still remains a challenge. These findings suggest that the genetic heterogeneity of both autism and epilepsy may produce similar deficits by bidirectional deviation from normal synaptic homeostasis at GABAergic or excitatory synapses. Future work using human neuropathology specimens and models especially those associated with neurodevelopmental abnormalities will further elucidate the molecular pathophysiological mechanisms of aberrant neurotransmitter receptors and their effects on signaling in autism alone, epilepsy alone, or patients with the autism and epilepsy phenotype.

Epinephrine

Alex Bonnin

Keck School of Medicine, University of Southern California, Los Angeles, CA, USA

Synonyms

Adrenaline; L-Adrenalin; L-Epinephrine; L-Epinephrine; Levo-Methylaminoethanol-catechol; Levoreninum; Lyodrin

Definition

Epinephrine is a catecholamine transmitter and hormone, generated from the amino acid tyrosine (or phenylalanine) in a common biosynthetic pathway with dopamine and norepinephrine. The enzyme tyrosine hydroxylase converts tyrosine to l-dihydroxyphenylalanine (l-DOPA). l-DOPA is then decarboxylated to dopamine by DOPA decarboxylase (DDC). Dopamine β -hydroxylase converts dopamine to norepinephrine. Finally, epinephrine is generated by N-methylation of norepinephrine, a process catalyzed by phenylethanolamine N-methyltransferase (E.C. 2.1.1.28, PNMT; Axelrod, 1962), utilizing S-adenosylmethionine as the methyl donor.

The adrenal medulla is the major site of peripheral epinephrine production. Once released in the blood, it causes systemic vasoconstriction and gastrointestinal relaxation, stimulates the heart, and dilates bronchi and cerebral vessels.

In the brain, epinephrine-producing (adrenergic) neurons were identified by their expression of PNMT. Immunohistochemical studies in animals have established several groups of adrenergic neurons (PNMT+) in the medulla oblongata: ventrolateral A1 and C1 cell groups, dorsomedial A2 and C2 groups, a rostral midline C3 group, and an additional unnumbered compact group in the dorsolateral portion of the nucleus tractus solitarii (nTS). PNMT-positive

neurons have also been mapped in the human medulla.

Epinephrine exerts its actions via three distinct types of adrenergic receptors: $\alpha 1$, $\alpha 2$, β . The $\alpha 1$ receptor class ($\alpha 1A$, $\alpha 1B$, and $\alpha 1D$ receptors) is coupled to Gq-type G-proteins. The $\alpha 2$ class ($\alpha 2A$, $\alpha 2B$, and $\alpha 2C$) of receptors is coupled to Gi-type G-proteins. The β class of receptors ($\beta 1$, $\beta 2$, and $\beta 3$) couples to Gs-type G-proteins.

Epinephrine is catabolized to the inactive compound L-metanephrine through the action of catecholamine-O-methyltransferase (COMT).

Episodic Memory

Diane M. Lickenbrock
Human Development and Family Studies, The Pennsylvania State University, University Park, PA, USA

Synonyms

[Autobiographical memory](#)

Definition

A subtype of the declarative memory system which stores personally experienced events (e.g., a memory of a specific place or time). Episodic memory is often associated with autobiographical context (e.g., remembering what happened on one's tenth birthday). This specific type of memory is assessed using a free recall task.

Research has shown that individuals with Autism Spectrum Disorder can have impairments in episodic memory.

Epistasis

Kai Wang

Department of Psychiatry and Department of Preventive Medicine, The Zilkha Neurogenetic Institute, Keck School of Medicine, University of Southern California, Los Angeles, CA, USA

Definition

In genetics, epistasis refers to the interaction between two or more genes, such that the phenotype differs from what would be expected if the genes exert their effects independently. The importance of epistasis has been increasingly recognized in human genetics in recent years, since it may be partially responsible for the “missing heritability” observed for complex diseases, that is, the aggregation of the marginal effects from genetic variants associated with a disease do not completely explain the heritability of the disease.

Historical Background

The term “epistasis” was first used by the English geneticist William Bateson in 1909 in his book “Mendel’s Principles of Heredity.” It was used to describe deviations from Mendelian inheritance patterns due to one gene masking the effects of another gene, that is, a particular variant in one locus prevents a variant at another locus from manifesting its effects. The book also popularized Mendel’s Law of Segregation and Law of Independent Assortment, originally conceived by Gregor Mendel in the eighteenth century and rediscovered in 1900. Bateson was also the first person to use the word “genetics” to describe the study of inheritance and the science of variation, and he codiscovered genetic linkage with Reginald Punnett.

There are many well-known examples of epistasis in genetics. One of the oldest examples

described in humans is on the expression of the ABO blood group system. Some individuals have a rare condition where they lack a protein called the H antigen. The H antigen is used to form A and B antigens, so these individuals cannot make A antigen or B antigen, and this scenario is often referred to as the “Bombay phenotype.” Individuals with Bombay phenotype can only be transfused with blood from other Bombay phenotype individuals. Even though these individuals with Bombay phenotype may have A or B genes, they cannot express the A or B blood group, and instead they appear to be blood group O. In this example, the H antigen masks the effect of the A or B genes, resulting in epistasis.

Another well-known example of epistasis is on genetics of coat color in mice. Two coat-color loci are involved in the control of coat color. At the first locus, having color (allele A) is dominant over lack of color (allele a). At the second locus, having the coat color agouti (allele B) is dominant over black (allele b). Consider a mouse that has homozygous aa alleles in the first locus: it will show no coat color, regardless of its genotype at the second locus (BB or Bb or bb). Thus, the variants at the first locus mask the effect of the second locus, and there is epistasis between the two loci.

It is important to emphasize that Bateson’s simple form of epistasis, as illustrated by the two well-known examples above, is merely a limited form of epistasis that works on Mendelian trait and is intuitively appealing to most biologists. However, a broader form of epistasis – from a population genetics perspective – involves more sophisticated statistical modeling and is more relevant for complex traits genetics. For example, two alleles at two different loci may each increase adult height by 1 cm on average, but when these two alleles occur together in the same individual, they may increase the height by 4 cm, which is more than what would be expected if the two alleles exert their effects independently. This broader form of epistasis is what typically emerges from current literature and is one of the hotly researched areas in genetics of complex diseases and traits.

Current Knowledge

Contribution of Epistasis to “Missing Heritability”

Genome-wide association studies (GWASs) have been very successful in identifying and replicating disease susceptibility loci for common and complex human diseases. These studies assay whole-genome SNP markers (typically 500,000 or more) for individuals grouped by different phenotypes (such as patients and control subjects) then test the statistical association between each marker and the phenotype. Top findings showing strong evidence of statistical significance are then replicated in another set of samples. As of December 2010, over 1,200 human GWASs have examined over 200 diseases and traits and found almost 4,000 SNP associations.

A question that often arises in GWAS is “where is the missing heritability?” The question refers to the fact that the collection of variants discovered in GWAS only explains a minor fraction of the heritability when simply added together, even for diseases or traits that are highly heritable. Multiple reasons have been proposed to explain the missing heritability, including (1) rare variants at known loci that act independent of common causal variants, (2) rare mutations in many thousands of loci, (3) copy number variants, (4) gene-gene interactions, (5) hidden environmental factors and epigenetic changes, and (6) wrong diagnosis of “common diseases.” Among these possible explanations, epistasis or gene-gene interactions could play a major role in contributing to “missing heritability,” since if the effect of one locus is masked by effects at another locus, power to detect the first locus is likely to be reduced and elucidation of the joint effects at the two loci will be hindered. If more than two loci are involved, complex multiway interactions may be present, further complicating the situation. For complex traits, given the known involvement of many contributing loci detected in GWAS, it is quite likely that epistasis will have to play a role. Therefore, it is reasonable to suspect that epistasis is a ubiquitous component of the genetic architecture of complex traits and diseases, such as neuropsychiatric and neurodevelopmental disorders.

Epistasis in Autism

Although several syndromes with single-gene causes, such as Rett syndrome and fragile X syndrome, share some phenotypic features with autism, it is widely recognized that autism is not a single-gene disease. Instead, the molecular pathophysiology of autism perhaps requires many genes in multiple biological pathways. However, the exact underlying genetic architecture for autism is still not well understood, and less is known on how different genetic components interact with each other. It is possible that rare, highly penetrant variants play a major role in each individual patient (oligogenic model), or it is also possible that thousands of variants, each with moderate effect sizes, contribute to autism pathogenesis. The first argument is supported by the observation that many highly penetrant mutations, especially large-scale deletions, have been enriched in patients with autism, although each patient may have different combinations of rare variants. The second argument is supported by the observation that sophisticated statistical approaches that utilize information from whole-genome markers, each with small effect sizes, can explain a large fraction of schizophrenia susceptibility. Besides these standing hypotheses, it is also possible that epistatic interactions play a major role in autism pathogenesis and that genetic variants with moderate effects sizes, when present in particular combination, will lead to much higher effect sizes that ultimately results in autism pathogenesis.

There are sporadic reports in literature on observed epistasis in autism susceptibility. For example, Coutinho et al. have tested for epistasis between loci with marginal effects in autism. In addition to the significant independent effects, evidence for interaction between SLC6A4 and ITGB3 markers was also found. The overall results implicate SLC6A4 and ITGB3 gene interactions in both autism etiology and in serotonin level determination, providing evidence for a common underlying genetic mechanism and a molecular explanation for the association of platelet hyperserotonemia with autism. With the wider application of GWAS and copy number variation studies, more epistasis may be observed in autism in the future.

Physical Interaction Versus Statistical Interaction

The word “interaction” is sometimes used to infer epistasis; however, there are two types of interactions in the contexts of genetics: physical interaction versus statistical interaction. Proteomics techniques, such as yeast two-hybrid systems, are now available to locate proteins that interact with one another in a protein complex. In these cases, proteins bind to each other, resulting in molecular functions that cannot be performed by each components of the protein complex. In contrast, statistical interaction summarizes genotype-phenotype relationships using population-level data rather than proteomic data. In fact, genes with statistical interactions do not have to physically bind to each other.

Statistical Methods to Detect Epistasis from Genetic Data

Mathematically, the quantitative genetic concept of epistasis may be represented for two loci by the linear model

$$y = u + a_1x_1 + a_2x_2 + d_1z_1 + d_2z_2 + i_{aa}x_1x_2 + i_{ad}x_1z_2 + i_{da}z_1x_2 + i_{dd}z_1z_2$$

where y is a quantitative phenotype and x_i and z_i are dummy variables related to the underlying genotype at locus i . The coefficients μ , a_1 , d_1 , a_2 , and d_2 represent genetic parameters that may be estimated corresponding to the mean effect, additive effect, and dominance effects at the two loci; i_{aa} , i_{da} , i_{da} , and i_{dd} correspond to epistatic interaction effects. Lack of epistasis in this model implies that all interaction coefficients are zero. In this case, the resulting model is

$$y = u + a_1x_1 + a_2x_2 + d_1z_1 + d_2z_2$$

where each allele exerts their effect independently with the effect size of a_1 , a_2 , d_1 , and d_2 , respectively.

In practice, it is more typical to assume a simple additive model where the effect sizes of a

homozygote doubles that of a heterozygote. Therefore, it is convenient to use a single variable x or z to denote the number of copies of the allele 2 present at the locus. The linear model can then be simplified as

$$y = u + ax + dx + i_{ad}xz$$

In this case, lack of epistasis in this model implies that i_{ad} is zero, that is, model will simply be

$$y = u + ax + dz$$

For binary traits, a logit function is typically used to model the response variable:

$$\begin{aligned} \log \text{it}(p) &= \log(p/(1-p)) \\ &= u + ax + dz + i_{ad}xz \end{aligned}$$

where the outcome of interest (such as probability of disease) is defined to be p .

It is important to note that besides these simple parametric linear models, other forms of modeling strategies also exist. There are unique advantages for using linear models as it is intuitively simple to interpret and it is relatively easy to implement. However, they may have limitations for detecting nonlinear patterns of interactions. For example, when many genes are involved in explaining complex diseases or traits, the number of predictor variables (genotype combinations) grow exponentially as each SNP is added to the model. Estimation of parameters in such linear models can be unstable and may easily result in overfitting the data. Additionally, linear models generally assume that genetic factors involved in interaction also exhibit independent marginal effects, but this may not be the case in reality (although it is not known how common it is for interaction to be present in the absence of any marginal effects). Nonparametric approaches, especially those involving modern machine-learning approaches, may have their unique advantages in specifically addressing these issues (see below).

Future Directions

The Role of Epistasis in Genetic Susceptibility to Autism

Despite the recent discovery of multiple common and rare genetic variants that confer autism susceptibility with different effect sizes, whether and how these genetic factors interact with each other is currently not known. Furthermore, the form of epistasis involved in autism pathogenesis may include both gene-gene and gene-environment interactions. Many environmental factors, such as air pollution and paternal age, have been linked to autism susceptibility in recent years, but whether these environmental risk factors function independently of genetic risk factors is an unexplored area of research. On the other hand, it is well known that certain environmental factors, including radiation, smoking, and older age, can increase the possibility of de novo genetic alterations, such as de novo copy number variants (CNVs). Given the known involvement of de novo variants in autism, it is highly reasonable to suspect that there may be gene-environment interactions that play a role in increasing genetic susceptibility to autism. This hypothesis needs to be tested in future larger scale genetic studies that also collect various aspects of environmental variables.

Testing Epistasis in Genome-Wide Level

In recent years, a large collection of methods have been developed to detect the presence of epistasis from population-level genetic data. By allowing for epistatic interactions between candidate disease loci, it may be possible to succeed in identifying genetic variants with weak marginal effects that may otherwise evade detection. In addition, some statistical or computational models for modeling genome-wide epistasis (such as support vector machine approaches and penalized regression approaches) can be easily adapted for prediction of phenotypes from genotypes, enabling the implementation of personalized disease risk predictions.

Although the importance of epistasis has been increasingly recognized, one may argue that it has

never really received the attention that it deserves in genetic association studies, especially in GWAS. The major reason is not the lack of methods to test epistasis per se, but the need to adjust the enormous burden of multiple testing, and the lack of appropriate biological interpretation to significant results. In typical GWAS with 500,000 SNP markers, testing genome-wide epistasis implies the need to test for approximately 250 billion hypotheses, even when considering only two-way interactions. The situation becomes worse when three-way or multiway interactions are considered. With the availability of massively parallel computational platform, this may no longer be a computational issue, but how to appropriately calculate the effective number of independent tests and accordingly adjust multiple testing is a problem without consensus on solution.

The Development of Bioinformatic Approaches

Although sophisticated approaches based on various forms of linear models have been used to detect epistasis in genome-wide scale, they may have some intrinsic limitations as discussed above. Therefore, novel approaches from the computational science arena, including machine-learning approaches such as random forests (RFs) and multifactor dimensionality reduction (MDR), have been developed to address these issues. Some of these approaches represent “black-box” modeling strategies: rather than fitting the data into a prespecified statistical model that the investigators believes in, these methods aim to let the data tell us what the appropriate model is. This is a rapidly growing area for methods development, and several recent reviews highlighted the advantage of these methods.

Biological Interpretation of Epistasis

When significant epistasis is found, the next natural question is how to interpret the results and

how to leverage this information to better understand the genetic architecture of complex diseases. Unfortunately, there is no easy answer to these questions. Many factors may blur the seemingly straightforward interpretation of the epistatic effects. For example, many modern genetic association studies use SNP markers, which rely on linkage disequilibrium to detect indirect associations. Since the marker allele most likely may not be the true disease allele, the detected epistatic effects could be due to the artifact of the imperfect tagging of the disease allele. Even worse, if the marker allele, being a common allele, is merely a proxy for multiple rare functional alleles (so-called synthetic association), then it will not be possible to tell which rare allele has epistasis with variants at another loci or whether the observed epistasis merely reflects a “synthetic epistasis” on multiple rare alleles. Therefore, significant statistical results may not always lead to a biologically sound explanation, and it is important not to overinterpret the statistical results.

In summary, direct biological inference from the results of analysis on epistasis can be very difficult. Compared to marginal effects of individual markers in association tests, the biological knowledge gained from investigation of epistasis, even in the presence of strong statistical evidence, can be quite limited. The most effective interpretation of epistasis probably depends on some levels of prior biological knowledge on the genes under investigation, as well as additional molecular evidence, rather than a pure statistical exercise on P values and effect sizes.

Equivalence-Based Instruction (EBI)

Bryan J. Blair^{1,2} and Michael F. Dorsey^{1,3}

¹Institute for Behavioral Studies, The Van Loan School, Endicott College, Beverly, MA, USA

²Long Island University, Brooklyn, NY, USA

³Amego Inc., The Best Clinical Network, Attleboro, MA, USA

Definition

Equivalence-Based Instruction (EBI) refers to procedures based on the behavioral principle of

stimulus equivalence (Sidman 1994). Stimulus equivalence classes are formed when stimuli that share no physical similarities become functionally equivalent to (i.e., substitutable for) each other (Green and Saunders 1998; Sidman 1994; Sidman and Tailby 1982). The term equivalence was borrowed from the field of mathematics (if $A = B$ and $B = C$ then $A = C$) to describe the emergent relational responding emitted by learners that was observed by early researchers.

An equivalence class consisting of three member stimuli (A, B, C), for example, forms when a learner emits the following nine responses of which only three are directly trained (Table 1 and Fig. 1): when presented with sample A (or B or C), the learner selects the identical stimulus (reflexivity or identity matching); after being

trained to select B when presented with A, the learner selects A when presented with B (symmetry); after being trained to select C when presented with A, the learner selects A when presented with C (symmetry); selecting B when presented with C (equivalence) and selecting C when presented with B (equivalence). Three or more classes of at least three stimuli are generally taught simultaneously (e.g., numbers, categories, types, etc.) (Table 2 and Fig. 2). For typically developing learners, these responses tend to emerge without the need for direct training. However, for learners with an Autism Spectrum Disorder (ASD), direct training is often necessary.

EBI procedures use a variety of specific training methods to teach a small number of skills

E

Equivalence-Based Instruction (EBI), Table 1 Alphanumeric labels of stimuli and responses and types of relations in a 3-member (A, B, C) equivalence class

Alphanumeric label	Sample stimulus	Selection response	Name of relation	Trained/tested

		Class		
Member		1	2	3
A	Printed numeral	7	8	9
B	Printed quantity			
C	Printed word	Seven	Eight	Nine

Equivalence-Based Instruction (EBI), Fig. 2 Example equivalence class diagram for the number/quantity “seven”

(typically matching or verbal responses) that result in the generation of an even larger number of emergent (i.e., untrained) skills. Training and testing methods may consist of conditional discrimination training (e.g., match-to-sample (MTS)), sorting, categorization, or verbal behavior training). EBI generally uses physical stimuli (e.g., laminated cards, objects, spoken, etc.); however, the instruction may also be delivered via a computer or mobile device.

Unlike stimulus generalization, in which a person’s responses occur in stimulus conditions that are similar to, but not the same as the conditions present during training, stimulus equivalence describes emergent, or derived relational responding. With stimulus generalization, a child might call every adult male “dad” after being taught that his father should be called “dad.” However, with stimulus equivalence, a child might learn that the written numeral “7” is functionally equivalent to a card with seven dots and also to the written word “seven,” and the

relations among all three members become substitutable (Fig. 2). Similar to stimulus generalization, these relations emerge as a result of the direct training of specific discriminations; however, unlike stimulus generalization, a person will emit the same responses when presented with stimuli that share no physical similarities, and this discriminative responding emerges without being directly taught.

Historical Background

Investigations and applications of EBI began in the 1990s and have continued across research sites, populations, settings, skills, and training methodologies (Rehfeldt 2011). EBI procedures are generally based on the principle of stimulus equivalence first identified by Sidman (1994). EBI research has sought to clarify some of the methodological questions that have naturally

arisen as it has been used with an increasing number of learners and skills. In addition, the use of technology (e.g., computer-based training and mobile applications) in the delivery of EBI systems has been an area of interest for researchers and educators.

There is some disagreement in the field of Applied Behavior Analysis (ABA) regarding the term EBI and its use to describe a number of similar instructional procedures; however, EBI is the most commonly used term to describe procedures where the explicit goal of instruction is the emergence of derived equivalence relations. The term has gained sufficient academic and clinical usage that the Behavior Analyst Certification Board (BACB) has included it in the 5th Edition of the Board Certified Behavior Analyst Task List (Behavior Analyst Certification Board 2017) as a required competency for practicing applied behavior analysts.

Rationale or Underlying Theory

There are several theoretical frameworks that attempt to account for the emergent responding seen in EBI. Sidman (1994) proposed that the observed emergent responding was a direct result of the contingencies of reinforcement and that no other behavioral principle was necessary to account for the untrained responding. However, others have argued that this explanation is insufficient to support the formation of equivalence classes. Hayes et al. (2001) argued for a new conceptualization of these emergent responses. The authors suggested that equivalence relations are merely one example of a vast array of derived relational responses (e.g., more, closer, taller, older, etc.). A third explanation for the emergence of derived responding is naming (Horne and Lowe 1996). The authors posit that a form of mediating (usually covert) verbal behavior is in some way responsible for the emergence of equivalence classes. However, for teachers and other practitioners, these different interpretations of the research are somewhat academic and do not significantly affect applications or the development of curricula.

Since the experimental identification of equivalence relations occurred in the 1970s, dozens of applied and translational studies have been conducted and published that replicated and extended the early laboratory observations of the formation of equivalence relations. However, like any established intervention or treatment, further investigation into specific learner characteristics, prompting procedures, training and testing parameters, fluency, generalization, maintenance, and application across settings continues.

Goals and Objectives

When compared to other teaching methods, the main goal of EBI is to teach skills in a more efficient way. With traditional methods, skills are usually taught to mastery, discretely, and then generalization and maintenance of the skills are tested. However, with EBI, a small set of skills is taught and the emergence of several other skills is then tested (including the maintenance and generalization of those emergent skills). For example, where a teacher might have previously used a stimulus fading procedure to establish relations between two stimuli, a teacher might now use EBI to establish an equivalence class. The underlying objective of EBI is thus to reduce the overall time required to teach skills by relying on the emergence of untrained skills.

Treatment Participants

EBI has been shown to be effective across a range of participants with a wide array of ages, functioning levels, and with children with developmental disabilities, specifically Autism Spectrum Disorders (ASDs). Published research has demonstrated the efficacy of EBI procedures for people with ASDs of all ages; however, the bulk of the research has been conducted with children. Research has been conducted on basic principles, protocols, and factors affecting mastery and efficacy of the procedures in well-controlled experiments using arbitrary stimuli in addition to applied skills and in clinical settings. Particularly, EBI has been shown to be effective in teaching

children with an ASD more efficiently, and EBI results in generative responding unlike with more traditional approaches to instruction (McLay et al. 2013).

Treatment Procedures

EBI is a general term that is used to refer to a number of component training and testing protocols, procedures, and structures. The most common method of training and testing is conditional discrimination training, specifically MTS. Other methods of training and testing have been shown to be effective including sorting, categorization, and verbal behavior (Jennings and Miguel 2017; Ma et al. 2016; Miguel et al. 2008). However, these procedures tend to be more difficult to prepare and implement in applied settings.

During MTS training, a sample stimulus and an array of comparison stimuli are presented and a selection response is prompted and reinforced, and during testing the response is generally not prompted or reinforced. Prior to training, pretests (i.e., baseline tests) are conducted to determine the learner's prior history with the stimuli. Then, certain discriminations (e.g., AB and AC) are trained and tests are conducted after training to determine if the derived responses (BA, CA, BC, CB) emerged. If a learner fails a test, remedial training for the trained relations is typically conducted. Posttests are then conducted to determine if an equivalence class has formed (i.e., all stimuli have become functionally equivalent).

Every sensory modality can be used with EBI training. Stimulus forms can include auditory (e.g., spoken), visual (e.g., pictures or written text), and tactile (e.g., physical objects). Similarly, several response forms can be trained including selection-based (e.g., selecting from an array of comparison stimuli, multiple choice questions) and topographical (e.g., vocal product, written, typed, drawn, etc.). It is recommended to use auditory stimuli as samples as it is impossible to simultaneously present multiple auditory stimuli as comparisons.

Green (2001) and MacDonald and Langer (2018) listed a number of best practices regarding conditional discrimination training and these

practices should be followed for MTS in EBI as well. The suggested methodological guidelines include:

- Fast-paced trial presentation
- Immediate reinforcement.
- Present a different sample stimulus every trial
- Have at least three comparison stimuli in an array
- Counterbalance the presentation order and positions of sample and comparison stimuli
- Require an observing response
- Auditory stimuli should be used as sample stimuli
- Prepare trials out of view of the learner
- Teach basic learner and readiness skills prior to using MTS
- Use errorless teaching or prompt-fading methods

Basic and applied research has also established best practices regarding EBI specifically. These include using a simple-to-complex training protocol and a one-to-many (OTM) training structure (Arntzen 2012; Saunders and Green 1999). A simple-to-complex training protocol describes a procedure where the AB and AC discriminations are taught followed by testing for the emergent relations. An OTM training structure is the term used to describe the method of specifically training the AB and AC discriminations as opposed to other combinations (e.g., AB then BC or AC then BC). Given that training and testing is usually selection-based, it is also recommended to test for the emergence of topographical responding (e.g., vocal tact, written response, etc.) where appropriate. And like all other behavior-analytic interventions, it is important to assess generalization (stimuli and settings) and maintenance over time.

Efficacy Information

EBI has been shown to be effective for a variety of skills in numerous settings with hundreds of learners in controlled experiments. In addition, dozens of published articles have established the

efficacy of EBI across a range of learners, ages, settings, ability levels, diagnoses, training procedures, stimulus parameters, and response topographies (Dixon et al. 2018; McLay et al. 2013; McKeel et al. 2015; Rehfeldt 2011). Given several published standards of the criteria for the identification of an evidence-based practice EBP (National Autism Center 2015; Wong et al. 2015), and given that EBI procedures are comprised of component instructional methods (e.g., discrimination training) that are well established as EBPs, EBI would be considered to be an EBP that can be used for the development of individualized curriculum for learners with ASDs.

Outcome Measurement

The defining feature of EBI is the establishment of emergent relational responding. This skill is easily observed and data can be collected in a variety of ways, including direct observation and electronically. In addition, procedural integrity assessments can be conducted, and interobserver agreement (IOA) and reliability data can be easily collected to ensure the validity of EBI procedures and the accuracy of accuracy and reliability of data collected from direct observations. Standard MTS data sheets may be used and data is commonly presented as a percentage of correct responding per sessions (either training or testing). The mastery criteria for the establishment of an equivalence class are generally between 90% and 100% correct for all trained and tested relations. Remedial training may be necessary in some cases. In addition to the establishment of equivalence classes comprised of stimuli used during training, generalization to novel stimuli that are also substitutable can be tested. Finally, test probes can be conducted periodically to determine if the skills maintain over time.

Qualifications of Treatment Providers

The underlying teaching protocols for most EBI programs are based on conditional discrimination training and MTS procedures. Most practicing

Board Certified Behavior Analysts (BCBAs) and/or Licensed Behavior Analysts receive academic and experiential training on conditional discrimination preparations and curriculum design. However, not all practicing BCBAs routinely use systematic and structured conditional discrimination training. Therefore, it is recommended that in addition to a BCBA or a License, that practitioners who wish to use EBI procedures gain some postcertification/licensure training (e.g., conference workshops, coursework, mentoring, etc.) before implementing EBI with their clients. That being said, the BACB's Task List - 5th Edition (Behavior Analyst Certification Board 2017), which will be the standard in 2022, includes EBI as a required skill that practicing BCBAs should be fluent with. Therefore, over the coming years, all graduate programs will include coursework specifically on EBI, and many supervised experiences will include direct training of EBI procedures. In addition, given the right amount of training, supervision, and support, teachers, parents, paraprofessionals, and caretakers should be able to implement basic protocols based on EBI.

Error Correction

Josh Pritchard¹ and Mark Malady²

¹Applied Behavior Analysis, Florida Institute of Technology, Orlando, FL, USA

²Florida Institute of Technology, Melbourne, FL, USA

Definition

In the applied autism literature, error correction is a procedure that details what a trainer or program implementer does when the learner engages in an incorrect response during a teaching opportunity. Error correction aims to enhance learning by teaching the learner the appropriate response and increasing the learner's contact with reinforcement contingencies rather than simply extinguishing errors. This procedure is intended

to help learners acquire skills much faster and with less frustration than simply allowing trial and error. In other words, it teaches the learner what *to do* instead of just allowing them to make mistakes and try to determine the correct response on their own.

There are three types of procedures for error correction. All three types are presented after the learner engages in a defined incorrect response (including no response within a specific amount of time) and are combined with a differential reinforcement procedure. Each of the three is defined independently below:

1. A procedure consisting of a series of response prompts following a learner's error to increase the probability of the learner immediately engaging in the target response.
2. A series of repetitions of the target response contingent on a learner's error, typically combined with a differential reinforcement procedure (Worsdell et al. 2005).
3. Manipulation of the stimulus or addition of a stimulus contingent on the learner engaging in an error, typically combined with a differential reinforcement procedure (Catania 2007).

The type of error correction in teaching approaches can vary substantially. For instance, some approaches use an “errorless” approach, in which they provide the correction (in the form of prompts) before or as soon as the incorrect response occurs. Other approaches utilize the “no-no prompting” correction in which they gradually increase the amount of error correction. Often these are chosen and tailored on the basis of the learner's skill level and learning goals.

Definition

The error-related negativity, or ERN, is an electrical brain signal measured with an electroencephalogram. Detectable at the scalp via the event-related potential (ERP), the ERN occurs when an individual makes a behavioral error. The ERN is typically evoked with simple cognitive tasks when an individual responds incorrectly or responds when a response should be withheld. The ERN manifests as a negative deflection in the ERP at approximately 80–150 ms following error commission, time-locked to an individual's response. The ERN is largest at central to frontal-central scalp regions. The most likely neural generator of the ERN is the anterior cingulate cortex, with converging evidence coming from

fMRI (Ito et al. 2003), EEG source modeling (Luu et al. 2003), and brain lesion research (Stemmer et al. 2004).

Definition

Free radicals remain an integral component of numerous physiological and pathophysiological activities within cellular systems. Free radicals result from electronic excitations leading to the creation of unevenly paired electrons which

react with biomolecules in three primary stages: initiation, propagation, and termination. In initiation, free radicals are produced through high-energy radiation, hemolytic cleavage, or the addition of excited electrons. Through propagation, free radicals produce additional free radicals through a process reminiscent of nuclear chain reactions. In the termination step, the propagation of free radicals may be eliminated when free radical species react with one another or are scavenged by antioxidant molecules. In biological systems, reactive oxygen species (ROS), such as $\bullet\text{OH}$ and $\text{O}_2\bullet^-$ are the most prominent free radical species produced from environmental exposure or cellular respiration (Devasagayam et al. 2004). Despite their destructive potential, ROS modulate numerous physiological activities, including the immune response, enzymatic activity, cellular signaling, and apoptosis (Devasagayam et al. 2004). Thus, the production of ROS is a highly regulated process requiring antioxidants to prevent, intercept, and repair free radical damage to lipids, proteins, and DNA (Devasagayam et al. 2004).

Free radical damage has been linked oxidative stress to numerous psychiatric conditions, including schizophrenia, major depressive disorder, anxiety, and obsessive-compulsive disorders (OCD) (Chauhan and Chauhan 2006). Increasing evidence suggests reduced antioxidant capacity from prolonged oxidative stress may underly ASD neuro-cognitive abnormalities (Parellada et al. 2012). Furthermore, proper neuronal differentiation and development requires a delicate balance and coordination between antioxidant and pro-oxidant cellular process (Fantel and Person 2002). As a result, researchers have investigated the correlation between ASD and several biomarkers for antioxidant status. In this regard, erythrocyte glutathione peroxidase (GSH-Px1) has shown significant promise (Kondolot et al. 2016; László et al. 2013; Paşca et al. 2006; Söğüt et al. 2003; Yorbik et al. 2002).

GSH-Px1 is an essential antioxidant which eliminates hydrogen peroxide to water using glutathione (GSH) and reduced NADPH as cofactors (Devasagayam et al. 2004). In a recent study, a negative correlation between homocysteine levels

and erythrocyte glutathione peroxidase activity was discovered among ASD patients (Paşca et al. 2006). The authors argued this trend matched previous studies showing elevations in homocysteine down-regulates GSH-Px1 and thus contributes to the pathogenesis of ASD (Paşca et al. 2006). In addition, several clinical studies showed a significant decrease in erythrocyte GSH-Px1 in ASD patients (Kondolot et al. 2016; László et al. 2013; Parellada et al. 2012; Yorbik et al. 2002). However, one clinical study showed an increase in erythrocyte GSH-Px1 activity resulting from previous cellular oxidative stress or compensatory mechanisms to decreased antioxidant defenses (Söğüt et al. 2003). Overall, ASD patients showed a consistent decrease in antioxidant status and free radical scavenging. Given these results, further investigation into antioxidant biomarkers may provide additional insight in the pathogenesis and treatment of ASD.

Escape Training

John Molteni

Institute for Autism and Behavioral Studies,
University of Saint Joseph, West Hartford, CT,
USA

Synonyms

Escape extinction

Definition

Escape training/extinction is a behavioral procedure that is generally used to treat escape or avoidance maintained behaviors. Utilization of

escape extinction procedures includes discontinuing the escape contingency upon the occurrence of the behavior. That is, when a behavior that is reinforced by negative reinforcement (removal of a stimulus contingent on a response that leads to an increase in that behavior), preventing escape contingent on that behavior will lead to a reduction in that behavior. Escape extinction has been demonstrated as being effective alone and as part of a treatment package for a variety of escape maintained behaviors. One area of emphasis in the research literature where escape extinction has been widely used is feeding interventions for individuals with selective feeding or food refusal. Escape extinction in the form of non-removal of the spoon (i.e., presenting the bolus of food within close proximity to the mouth of the participant until the food is accepted) is one example of escape extinction. Extinction procedures have several potential side effects including the extinction burst – an immediate increase in the frequency or intensity of behavior following the discontinuation of reinforcement – extinction-induced aggression—an escalation in aggressive behavior and spontaneous recovery, that is, a return to higher levels of the target behavior after a behavior has been reduced to low levels. In order to address the potential side effects of extinction, use of reinforcement-based procedures (e.g., reinforcement of food acceptance in the above example) is strongly recommended. Behaviors can demonstrate resistance to extinction, meaning that the behavior will persist even when the reinforcement for that behavior has been removed. There are several factors that may contribute to this resistance including the level of motivation for the reinforcer (i.e., the higher the value of the reinforcer, the more resistant it is to extinction), the schedule of reinforcement, the alternative sources of reinforcement for the same behavior, the amount of effort required to emit the behavior (i.e., the higher the effort the less resistant to extinction), and whether the behavior has been under extinction before with rapid decreases with each application of extinction. Use of extinction is not recommended when the individual engages in high-intensity behavior such as dangerous aggressive and self-injurious behavior as

an increase in the intensity of behavior would lead to risk of injury to the individual or others.

Escitalopram

Carolyn A. Doyle¹ and Christopher J. McDougale^{2,3}

¹Indiana University School of Medicine,
Indianapolis, IN, USA

²Lurie Center for Autism, Massachusetts General Hospital, Lexington, MA, USA

³Nancy Lurie Marks Professorship in the Field of Autism, Harvard Medical School, Boston, MA, USA

Synonyms

Brand names: [Anxiset E \(India\)](#); [Cipralext \(Canada\)](#); [Lexam](#); [Lexamil](#); [Lexapro](#); [Seroplex](#)

Indications

According to the official prescribing information, escitalopram is FDA-approved to treat major depressive disorder (MDD) in adults and in adolescents aged 12–17 years old, both acutely and as maintenance therapy (Forest Pharmaceuticals 2011). It is also approved for the acute treatment of generalized anxiety disorder (GAD) in adults. It is not approved for children under the age of 12 years.

Escitalopram is not approved for the treatment of autism spectrum disorders (ASDs). ASDs include the DSM-IV-TR diagnoses of autistic disorder, Asperger's disorder, and pervasive developmental disorder, not otherwise specified (PDD-NOS). The decision to use escitalopram in the treatment of established clinical indications that may co-occur with ASDs, as mentioned above, or for commonly observed symptoms of ASDs, such as hyperactivity, inattention, irritability, aggression, repetitive behaviors, and social impairment, can be made on an individual basis by the treating practitioner. This will be discussed in more detail in the “Clinical Uses” section.

Mechanisms of Action

Escitalopram is a selective serotonin reuptake inhibitor (SSRI). Normally, serotonin is released from the presynaptic axon terminal to travel across the synaptic cleft and attach to the postsynaptic axon terminal. Any excess serotonin remaining in the cleft is picked up by the serotonin reuptake transporter in the presynaptic axon to be degraded and recycled. It is hypothesized that a depletion of serotonin available to act on the postsynaptic axon results in symptoms experienced in some mood and anxiety disorders, including sadness, nervousness, guilt, loneliness, apathy, and avolition. Escitalopram attaches itself to the serotonin reuptake transporter and prevents whatever serotonin remains in the cleft from being taken back up in the presynaptic neuron. The excess serotonin is free to attach to postsynaptic receptors and exert its intended effects.

Escitalopram begins acting immediately to inhibit serotonin reuptake, but like other SSRIs, its antidepressant and anxiolytic effects are often not experienced for up to 6–8 weeks. This is thought to be due to gradual changes SSRIs make on serotonin receptor sensitivity. It is believed that the decreased amounts of serotonin found in mood and anxiety disorders cause the postsynaptic axon to upregulate the number of postsynaptic axonal receptors expressed. In other words, a decreased amount of serotonin in the synaptic cleft results in an increased amount of receptors at the ready. When escitalopram enters the picture, the level of serotonin in the cleft rises. Postsynaptic receptors respond to the serotonin increase and send messages to the axon nucleus about the changes in the synaptic cleft. The nucleus begins downregulating the amount of serotonin receptors ready to receive serotonin. These changes are gradual and are believed to take 6–8 weeks before being fully completed, reflecting the amount of time before many patients begin feeling relief from their symptoms.

Like other SSRIs, escitalopram's antagonism of the postsynaptic 5-HT_{2C} receptor results in some of its unique therapeutic effects. When serotonin attaches to the 5-HT_{2C} receptor, it blocks the release of neurotransmitters norepinephrine and dopamine in the brain. When escitalopram blocks the postsynaptic 5-HT_{2C} receptor, norepinephrine and dopamine are instead released and exert their effect in the prefrontal cortex. The effect is activating, often leading patients to feel more energized and less fatigued, with improved concentration and attention. Escitalopram's effects can also be described as anxiolytic, and it is currently FDA-approved for the treatment of GAD. Escitalopram is often considered the “quintessential SSRI” as it only contains the S enantiomer, unlike the related compound citalopram (Celexa), whose racemic makeup includes both R and S enantiomers. (Enantiomers are a pair of chemical structures that exist as mirror images and subsequently exert different effects.) Escitalopram's lone S enantiomer yields a “purer” serotonin reuptake inhibition response and removes some side effects that exist in the racemic (mixed) compound. This unique property allows for escitalopram to be more

efficacious at lower doses given the absence of a potentially interfering R enantiomer. The lack of CYP450 enzyme interactions makes escitalopram one of the best tolerated of the SSRIs, although it is not yet generic and therefore can be expensive.

Specific Compounds and Properties

(S)-1-[3-(dimethylamino)propyl]-1-(4-fluorophenyl)-1,3-dihydroisobenzofuran-5-carbonitrile.

Clinical Use (Including Side Effects)

FDA-Approved Clinical Uses

In adults, escitalopram is FDA-approved to treat MDD, both acutely and as maintenance therapy, and for the acute treatment of GAD (Forest Pharmaceuticals 2011). Per the official prescribing information, escitalopram is typically started at 10 mg once daily for the treatment of MDD with a recommended maximum of 20 mg daily. If the dose is increased to 20 mg once daily, it should occur after a minimum of 1 week. For GAD in adults, the recommended starting and target dose is 10 mg once daily. The goal of treatment is complete remission of symptoms and prevention of future relapses, so escitalopram is taken both throughout and in between clinical relapses (Stahl 2009). Although escitalopram can eliminate symptoms while being taken, it does not cure MDD or GAD, and symptoms can reoccur after the medicine has been stopped. If escitalopram is to be discontinued, a gradual dose reduction is recommended (Forest Pharmaceuticals 2011). After the first episode of depression in the treatment of adults with MDD, escitalopram should be taken for 1 year following symptom relief (Stahl 2009). After the second or any subsequent episodes of depression, treatment with escitalopram may be indefinite to avoid relapse of symptoms. Treatment of GAD may also require indefinite treatment.

Regarding the pediatric population, escitalopram is FDA-approved for the treatment of MDD in adolescents aged 12–17 years (Forest

Pharmaceuticals 2011). There are no clinically approved uses of escitalopram for children under the age of 12 years. In the treatment of adolescent MDD, escitalopram is typically started at 10 mg once daily with a recommended maximum of 20 mg daily (Forest Pharmaceuticals 2011). Per the official prescribing information, if the dose is increased to 20 mg once daily, it should occur after a minimum of 3 weeks.

Clinical Uses of Escitalopram in Autism Spectrum Disorders

Regarding pediatric populations, there is minimal evidence to suggest the effectiveness of escitalopram in children and adolescents with autism. Interestingly, antidepressants have been the most commonly prescribed psychotropic medications in treating symptoms associated with ASDs (Aman et al. 2005). Given the frequent use of SSRIs in autism, it is imperative that prescribing clinicians balance the benefit of such medications in lieu of their side effects. In 2004, the FDA released safety warnings about the increased risk of suicide-related behaviors in children and adolescents taking SSRIs, which subsequently curtailed the prescribing of SSRIs to this population (Nemeroff et al. 2007). The decision to use escitalopram in the treatment of established clinical indications that may co-occur with autism should therefore be made on an individual basis by the treating practitioner after careful consideration of the available data.

There are currently no published randomized, placebo-controlled trials examining the use of escitalopram in treating symptoms associated with ASDs. Therefore, minimal conclusions can be drawn about the efficacy of escitalopram in treating both adults and children with ASDs. Among the available research, a study by Owley et al. (2005) attempted to shed light on this subject. This prospective, open-label study included 28 children (25 males, 3 females) diagnosed with an ASD (71% with autistic disorder) between the ages of 6 and 17 years. They received escitalopram over the course of 10 weeks, which was increased to a maximum dose of 20 mg/day as tolerated. This study concluded that escitalopram

was “useful in treating some difficulties associated with pervasive developmental disorders (PDDs)” as evidenced by a 61% response rate, improvement in the areas of irritability (the most improvement), hyperactivity, lethargy, stereotypy, and inappropriate speech, and “significant improvement” via the Clinical Global Impressions scale. Again, a prescriber should be cautious in generalizing these results to the larger population of patients with ASDs given the study’s design and small sample size which limit its interpretation.

Side Effects

Escitalopram is often considered the most tolerated of the SSRIs due to its simplified chemical structure, which potentially results in “purer” inhibition of the serotonin transporter and fewer cytochrome P450 enzyme-mediated drug interactions (Stahl 2008). Stimulation of serotonin receptor subtypes (5-HT_{2A}, 5-HT_{2C}, 5-HT₃, and 5-HT₄) in various parts of the brain likely causes many of the SSRIs’ observed side effects. A small amount of increased synaptic serotonin shortly after initiating therapy is often enough to cause some side effects, even if the clinical benefit is not yet apparent to the patient. Therefore, it is possible that side effects may be experienced earlier than symptom relief when first starting treatment with escitalopram (Stahl 2008). Side effects experienced may also be dose dependent (i.e., they increase as the dose increases) or time dependent (i.e., they start right after taking the medication but diminish with time) (Stahl 2009).

Patients who are treated for MDD are at increased risk for experiencing suicidal thinking and behavior. Antidepressants as a class have been shown to increase the risk of suicidal thinking and behavior in children, adolescents, and young adults (ages 18–24) with MDD and other psychiatric disorders (Forest Pharmaceuticals 2011). Such risk should be carefully considered when prescribing escitalopram in the pediatric and young adult population. Escitalopram is currently not approved for use in children younger than age 12 years. According to Stahl (2009),

gastrointestinal side effects are common and can include decreased appetite, nausea, diarrhea, constipation, or dry mouth. Sexual dysfunction is a common side effect in both males and females and is due to the effect of increased serotonin in both the brain and the region of the spinal cord regulating sexual response. In males, this includes delayed ejaculation, erectile dysfunction, and decreased sexual desire. In women, this includes decreased sexual desire and anorgasmia. Central nervous system side effects include insomnia or sedation, agitation, tremors, headache, and dizziness or lightheadedness. Patients with undiagnosed bipolar or psychotic disorders may be vulnerable to the activating properties of escitalopram, resulting in hypomania, mania, or psychosis. Patients may also experience vasodilation, dry mouth, diaphoresis, or abnormal vision. Increased serotonin can lead to diminished dopamine release, which may lead to emotional flattening, apathy, and cognitive slowing in some patients. Escitalopram has not been shown to result in clinically important body weight changes (Forest Pharmaceuticals 2011).

Of note, SSRIs have been found to yield side effects in people with ASDs, particularly agitation, hyperactivity, aggression, and insomnia (Posey et al. 2006). Extrapyramidal symptoms (Sokolski et al. 2004) and hypomania (Damore et al. 1998) have also been observed in case reports. These results are limited by a lack of placebo-controlled studies, although there is some evidence to suggest that children with ASDs may be more likely to develop such side effects relative to adults with ASDs (Posey et al. 2006).

Establishing Operations

Susan A. Mason

Services for Students with Autism Spectrum Disorders, Montgomery County Public Schools, Silver Spring, MD, USA

Definition

Establishing operations (EOs) are “events that alter the value of a reinforcer” (Michael 1982). EOs are sometimes called motivating operations (see MOs) (Vargas 2009). EOs can be conditioned or unconditioned. They may exist in many forms and often are reliant on states of deprivation; however, it is important to note that just as deprivation is experienced throughout the day, aversive stimulation is also common in our environment. Vargas (2009) noted, “Aversive situations are establishing operations for avoidance/escape behaviors.” Another form of establishing operation is known as “value altering.” In this situation, a stimulus or set of stimuli function to make the reinforcer more reinforcing. For example, effective advertising increases the desire to have the product being advertised; advertising is not reliant on a state of deprivation, and in a sense, it may create an aversive situation if everyone else has the item that is advertised and the person who does not have the item stands out because they are “different.” Key components of EOs are that an establishing operation “precedes the response it is functionally related to and it increases the effectiveness of a particular stimulus change as reinforcement” (Peterson 1978). In sum, an establishing operation determines what a person wants at any given time, and it is dynamic in nature because establishing operations is always changing (Cooper et al. 2007).

Historical Background

Historically, Skinner (1953) introduced the concept of EOs in his first publications when he wrote about a “third variable”; however, it was Keller and Schoenfeld (1950) who first coined the

term “establishing operations” (Vargas 2009). Establishing operations have been discussed extensively in the literature on verbal behavior and are independent variables that have been present in the study of applied behavior analysis since its inception. Experimental analysis of behavior and applied behavior analysis have both been concerned with complex ways of arranging reinforcers to change behavior (Bailey and Burch 2002).

Rationale or Underlying Theory

As stated earlier, EOs change the value of a reinforcer. In a classroom situation, this is especially important as we want learners to acquire new skills. Ensuring specific states of deprivation, or altering the value of a reward such that it functions as a powerful reinforcer, enhances the potential for positive learning outcomes. In the field of autism, establishing operations play an important part for increasing verbal behavior, especially when teaching manding (requesting). When there is a strong establishing operation in place, there is an increased likelihood that the target behavior will be demonstrated in order to access the reinforcer. Accessing the reinforcer, in turn, strengthens the response and increases the likelihood that it will occur again under the same or similar conditions.

Goals and Objectives

As noted previously, the goal of using EOs is to alter the value of a reinforcer such that the target response will be more likely to occur. Use of EOs increases the effectiveness of a particular stimulus change as reinforcement. EOs play an important role in behavior change.

Treatment Participants

Studies that examine the effects of EOs have been executed and replicated for years and have focused on many different populations in the research from animals to human beings. The examination of EOs has been particularly

prevalent in the research conducted on verbal behavior and, of late, has included studies focused on teaching persons with autism spectrum disorders to request desired items. Research has also focused on aberrant behaviors of persons with severe disabilities who engage in self-injury, aggression, and pica (McGill 1999).

Treatment Procedures

EOs have been included in such treatment procedures such as (a) extinction, (b) noncontingent reinforcement, (c) multicomponent treatment packages, (d) social attention (behavioral momentum), (e) functional communication training, (f) naturalistic/incidental language training, and (g) social-positive, social-negative, and automatic reinforcement (McGill 1999).

Efficacy Information

Large quantities of research exist to point to the efficacy of EOs within the context of reinforcer delivery. Researchers have demonstrated the salience of student choice in increasing the value of a reinforcer (Mason and Egel 1995; Mason et al. 1989; Lerman et al. 1997), varying the presentation of the reinforcer (Egel 1980, 1981), states of deprivation versus satiation (Volmer and Iwata 1991), properties of sensory stimuli as reinforcers (Ferrari and Harris 1981; Rincover and Newsom 1985), attention as an establishing operation and reinforcer during functional analysis (Fisher et al. 1997), teaching students with autism to mand for social information (Shillinsburg et al. 2016; Gutierrez et al. 2007), and effects of conditioned establishing effects on stereotypy (Lanovaz et al. 2014). Each of these studies has demonstrated that EOs are intimately linked to what a person wants at any given time, and in so doing, establishing operations affect the potency of the reinforcer.

Outcome Measurement

Current outcome measures for EOs support their importance across a variety of research

applications. Quantitative data collected during research regarding EOs has repeatedly proven that EOs have an impact on behavior change. EOs have been examined in the context of teaching language and communication to students with autism as well as other disabilities. They also have been examined within the context of other studies of verbal behavior as well as reduction of aberrant behaviors such as self-injury, pica, and aggression. Although the bulk of research that has been conducted involves single-subject research design, the quantity of replication across behaviors, subjects, and settings speaks to the validity of EOs in the context of examining reinforcers and reinforcement.

Qualifications of Treatment Providers

Although not explicitly stated in the research, persons who provide reinforcers in the context of teaching and/or behavior change projects should be knowledgeable in the field of applied behavior analysis and/or experimental analysis of behavior. Careful examination of the effects of any behavior change procedure should be closely monitored through data collection and analysis; modifications should be implemented according to data analysis. As such, qualified behavior analysts are providers that can use EOs within the context of educational procedures and behavior change procedures. Special education and general education teachers and paraprofessionals are capable of implementing reinforcement procedures under the guidance of a qualified behavior analyst.

Estate Planning

John W. Thomas

Independent Educational Consultant, Durham, NC, USA

Quinnipiac University School of Law, Hamden, CT, USA

Definition

In General

“Estate planning” refers to one’s instructions for the distribution of assets after one’s death, and includes the establishment of a will and/or trusts, and the gifting of property. Estate planning also includes preparing a plan for the care of a child who will need assistance after the parents or other caregivers have died.

Planning for Children with Disabilities, Generally

Thoughtful estate planning for children with disabilities utilizes all resources, private and public, to optimize the child’s security and quality of life. Actors involved in the planning process should include the parents and other caregivers, social workers, disability law lawyers, financial planners, and others who possess relevant skills.

Subjects of the estate plan should include economic resources, living arrangements, caregiver selection, and estate management.

Planning with Private Assets

Private assets include all property, both real and personal, and life insurance. Private assets can be managed through the creation of trusts and the

designation of a manager or conservator of the funds. The trusts instruments can include living trusts, created while the parents and/or caregivers are alive, or testamentary trusts, created upon death. One can direct distribution of assets by will.

Planning with Public Assets

Public assets include Medicaid, which covers health care, and Supplemental Security Income (SSI), which provides “a minimum income” for qualifying individuals, including the disabled. Federal law defines “disabled” for purposes of SSI eligibility as, “the inability to engage in any substantial gainful activity by reason of any medically determinable physical or mental impairment which can be expected to result in death or which has lasted or can be expected to last for a continuous period of not less than twelve months.”

Social Security also provides benefits relevant to estate planning for one’s disabled child. The program provides benefits to an adult child “when that parent retires, becomes disabled, or dies.” The child must have a disability that manifested before the age of 22, be unmarried, and have been dependent on the person who earned the Social Security benefits.

Ethics

Pat Walsh

Centre of Medical Law and Ethics, Dickson Poon School of Law, Somerset House East Wing, Kings College London, London, UK

Definition

Broadly speaking, ethics is the philosophical study of how we ought to live and what kinds of people and societies we ought to be or become. While the term sometimes refers to the systematic study of reasoning about how we ought to act often called moral philosophy, ethics is also concerned with matters of the most fundamental practical import. Central among its questions are those to do with how, as individuals and societies,

we ought to treat others, why we ought to treat them in that way, how we should evaluate the motives underlying actions, and our responsibility for the predictable consequences of our actions and policies. The various answers to questions of this sort often depend on different general viewpoints drawn from moral theories such as deontology or consequentialism or from various religious perspectives, all with their different metaethical and ontological assumptions. In addition to this philosophical input, reflection on many ethical issues, such as those raised by autism spectrum disorders, should be informed to a large extent by empirical research in order to identify and clarify what the relevant issues are.

However, a continuing lack of knowledge about the biological causes of autism and its neurobiological bases means that there is a corresponding uncertainty about the identification and resolution of the moral issues specific to autism and about how much illumination can be drawn from more general and established ethical discourses such as those concerning disability rights or reproductive ethics. Given the current state of knowledge about autism, there are actual and emergent ethical issues relating to its diagnosis and categorization, its prevention and cure, its treatment, and its associated research practices and agenda. All of these ethical concerns tend to have both conceptual and empirical aspects.

Historical Background

As a neurobiological developmental condition, what we now call autism has almost certainly always existed in the human population. However, it was only identified as a distinct condition in the mid-twentieth century. Hence the concept of autism has a relatively short history. From the 1940s until the 1980s, autism was understood as a categorical condition affecting a relatively small number of people and characterized by a distinctive set of behavioral features such as severe delays in language, impaired cognitive skills, and a profound lack of emotional contact with others. The goal of therapy at that time was largely to “free” the child from the shell of

isolation imposed by autism. Later, this psychological account was replaced by the idea of autism as a biologically based problem. Treatment and research strategies changed accordingly while preserving the goal, assumed to be ethically straightforward, of its remediation. In the last three decades, a new body of knowledge has emerged from studies documenting the complex pattern of strengths as well as weaknesses present in autism and from autobiographical writings by people with autism, such as Temple Grandin. The introduction in the 1980s of the idea that autism is best understood as a spectrum condition was an attempt to capture the heterogeneity of autism and the many ways it is experienced by those affected and remains hugely influential in thinking about autism (Wing 1981). Currently a growing appreciation by researchers of the sheer heterogeneity of autism and the speculative nature of much of the science in this area has led some to suggest that rather than one unique phenomenon, there may be different “autisms,” with different underlying biological processes and developmental pathways (Happé et al. 2006; Volkmar et al. 2009). Some even suggest that “autism” could be understood as an umbrella term for numerous different conditions (Coleman and Gillberg 2012). Clearly, then, while autism is not a new condition (or range of conditions), the understanding and concept of autism are relatively new, still evolving, and currently quite contested – all of which reservations enter into the ethical debate about autism.

Current Knowledge

One of the major difficulties in identifying and clarifying the ethical issues raised by autism is the sheer range of ways in which the condition manifests itself. Unfortunately, the general public remains largely unaware of this level of complexity. An increasing current cultural fascination with autism is fed by representations of it established by books like *The Curious Incident of the Dog in the Night-Time* and iconic films like *Rainman*, where the savantism of the main autistic character has led many people to believe that people with

autism generally possess similarly unusual talents. In reality, the majority of diagnosed individuals sit at different points along the spectrum at different times and in different contexts, rather than occupying a static position at or near its extreme ends. Among the possibilities the idea of a spectrum attempts to capture is the autistic individual who is profoundly intellectually impaired and nonverbal, the one who is extremely disabled but has unique strengths in an area such as art, music, or mathematics, or the one who is able to work effectively in solitude but is overcome by serious social difficulties when asked to work in direct contact with others. Moreover it seems the position of an individual on the spectrum is not necessarily fixed through the course of their life, because the condition is developmental and because individuals may learn social and adjustment skills that may minimize their symptoms. Adding to this complicated picture, it seems that in any given period, an individual with autism may fit behavioral descriptions of both “high” and “low” functioning, in different respects and even in different settings. In comparison with other recognized disabilities then, autism seems unique in the sheer range of its symptoms and behaviors, in the relatively plastic nature of its symptoms (especially early in life), and in the possibility of movement along a wide spectrum through the course of life. Given this level of complexity, it is not surprising that the idea of a spectrum cannot capture all the variabilities in the manifestation of autism symptoms and the differences in health, developmental difficulties, and sensory problems that contribute to the different profiles of people affected by autism.

Compounding the difficulties for the spectrum idea is the problematic high-functioning/low-functioning distinction it encourages. In the diagnostic context, for instance, people with autism are often viewed as occupying a point somewhere on a broad spectrum from low to high functioning, reflected by, for example, the range in IQ from severe intellectual impairment to high IQ, or in communication styles from no speech or language use to high, often eccentric articulacy, associated with the condition. Though this distinction has passed into current popular understanding and

descriptions of autism, no such categories are mentioned in the *Diagnostic and Statistical Manual of Mental Disorders* (DSM), and there seems to be little scientific evidence to justify categorizing autistic people along these lines. The fact that most individuals with autism will move between these categories depending on context, circumstances, and the expectations placed on them means the distinction fails to capture an important reality about autism and therefore is doing little useful explanatory work. To some extent, the latest edition of the DSM (DSM-V 2013) sidesteps some of these difficulties by introducing levels of severity of autism (mild, moderate, and severe) based on social communication impairments and restricted repetitive patterns of behavior with three levels – individuals with autism may (1) require support or (2) require substantial support or (3) require very substantial support. Hence how an individual is categorized depends on his or her specific abilities to function across a broad range of contexts. Difficulties remain, however, to do with the assumption that autistic individuals function at the same level across all areas (ASAN 2017). Presumably the heterogeneity of autism described means that individuals will move between these categories of severity and necessary level of support, just as they were said to move between high and low levels of functioning.

The fact of heterogeneity presents obvious difficulties for identifying appropriate medical and educational interventions, but it also hugely complicates ethical questions about how we should regard those affected by autism and how we should respond to and intervene in their lives. Hence it is to be expected that any appropriate ethical judgment about autism will tend to be cautious, provisional, and open to much qualification.

One example of this is provided by the process of diagnosis. Initial diagnosis may provide the occasion, whereby individuals and their families come to understand for the first time the reason for the problems they have been experiencing, and importantly, it may serve as the mechanism through which they can access the range of interventions and supports that are available. On the other hand, it currently confirms someone as

a person with a neurologically based disorder, with all the implications of that for how the individuals view themselves, how others view them, and how they are viewed by services, teachers, employers, and so on. The clear moral seriousness of this is compounded by difficulties in making the diagnosis secure. First, in not a few cases, there will be the difficulty, implicit in the notion of a spectrum, of establishing a nonarbitrary cut-off point between behavior considered “normal” or “mildly eccentric” and behavior considered “disordered.” Second, in many more cases, the general difficulty of applying the accepted criteria with confident objectivity will be felt. The diagnosis of autism currently involves assessing an individual’s developmental history and patterns of behavior against purely behavioral criteria as set out in the internationally recognized diagnostic manuals, the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-V 2013) and the *International Classification of Diseases* (ICD-10 2010). Though minimal, these criteria are arrayed in complex ways such that there is no behavior or set of behaviors that unequivocally denote autism. Because the genetic and neurobiological bases of autism are as yet largely unknown, no more objective physical tests are available to the diagnostician. That lack has led to an intensive search for biological markers, which, in addition to shedding light on the causes of autism, might also be clinically useful in complementing and improving its behavioral diagnosis and in enabling its earlier detection. To date, comparatively little has been achieved in identifying biomarkers with clinical utility – though *if* they are found, they may well pose new ethical challenges in the field of autism (Walsh et al. 2011). It is clearly morally important that diagnostic dialogues should acknowledge these various difficulties and uncertainties to everyone concerned.

Asking whether those dialogues should not also include references to the positive aspects of autism brings a fundamental and profound question into focus: what value should be placed on autism as a condition, and on different aspects of the condition? Is it enough, or even correct, to characterize autism solely as a disability and, as such, something to be prevented or cured where

medically and ethically possible? The challenge here is to the prevailing “deficit model” of autism propagated by the exclusively negative character of the criteria in the diagnostic manuals. The “impairment” in question is characterized by examples of “failure,” “lack,” and “stereotyped,” “repetitive,” and “abnormal” behaviors for instance. While it can be argued that is required in order to secure services, nonetheless the wholly negative characterization of autistic behavior can be seen as implicitly evaluative and question-begging, rather than scientific. Unfortunately it has enormous influence on clinicians, researchers and research agenda alike. The challenge to the deficit model also extends to the many forms of treatment and intervention that, following the reasoning that guides diagnosis, focus strongly on counteracting behaviors taken to be undesirable. Whether in diagnosis or in treatment, there seems to be a good case for understanding, assessing and describing aspects of autism more positively: instead of deficits we find instead strong persistent interests, attention to detail, and unusual memory, as well as heightened skills that are associated with some forms of autism, such as great visual acuity, perfect musical pitch, and remarkable mathematical prowess. (Walsh 2010; Baron-Cohen et al. 2009).

Nevertheless, the idea that autistic behavior can be most helpfully understood in terms of a “triad of impairments” in communication, imagination, and social interaction, which emerged in the late 1970s, has been the impetus for many influential theoretical developments (Wing and Gould 1979). Psychologists have attempted to explain each of these fundamental deficits, with the aim of clarifying the forms of treatment that could ameliorate and compensate for them. According to one theory, people with autism lack a “theory of mind” in being unable to understand the perspectives and points of view of other people (Baron-Cohen 1995). A second “executive function” theory explains some aspects of the repetitive behaviors seen in autism as an inability to plan sequences and actions (McGregor et al. 2008). A third “weak central coherence” theory is based on the idea that people with autism cannot process differences in a manner that makes them

cohere into a general pattern (Frith 1989). Each of these deficit views of autism has moral as well as scientific and practical implications. Some philosophers, for instance, have taken the first of these theories in particular – the view that people with autism are “mindblind” – as posing a legitimate query as to whether they have the full moral status of “persons” (Barnbaum 2008). The argument draws on a putative distinction between the concepts “human being” and “person” which gained currency in bioethical debates about the moral permissibility of abortion in the 1970s. Being genetically human, it was (and is) argued, is a morally neutral fact, while the term “person” identifies those *morally* important features of beings, including human beings, that should guide our estimate of their moral status and, thereby, our thinking and decision-making in their regard. Features of persons said to provide reasons for regarding them as subjects of moral concern and bearers of the fundamental protection of rights vary but centrally include consciousness, self-consciousness, a capacity for rational decision-making, and a capacity to communicate. In possessing none of these characteristics, it is argued, for example, that a human fetus is not a person in this sense and that abortion may therefore be morally permissible. The same distinction has since been sometimes considered in relation to people in a persistent vegetative state and the severely demented and their treatment. In regard to autism, it is suggested that the lack of a functioning theory of mind means people with autism are unable to recognize that others have beliefs, preferences, emotions, and desires independent of their own. The resulting purported lack of empathy leads to an inability to relate to others as persons and to enter into meaningful reciprocal relationships with them. Even more fundamentally, being mindblind may mean they are not able to reflect on their own mental states. On this view of the matter, at least some autistic people fail on two of the criteria of personhood. Though undoubtedly conscious, they may not be conscious of other people in the meaningful ways central to human relationships, and they may not be self-conscious in the ways necessary to qualify for moral personhood.

The more general question of the value to place on autism is also seen as having to engage with philosophical discussions of the conditions necessary for a good or flourishing human life. Most accounts of these conditions give a central place to the emotions, including particularly having personal relationships and a sense of affiliation with other people (Nussbaum 2006). Many of us (including many autistic people) would agree that friendship, for example, is an essential contributor to our well-being and recognize that autistic people have particular difficulties in this area. However, it is sometimes argued that individuals who lack a theory of mind, like those with autism, simply cannot live a full flourishing human life because their inability to empathize compromises their friendships and their sense of affiliation with others.

What might be said in response to these suggestions of the severe limits on the value of autistic life, said to follow from the deficit account of “mindblindness”? First, it is extremely important to remember that “mindblindness” is a *metaphor*, not a statement of fact, and that metaphors can be harmful and also incorrect. The most we can infer using this metaphor is that autistic people sometimes behave *as if* they were mindblind (Smukler 2005). Second, if this deficit hypothesis is not valid – not correct or only partly correct – none of the ethical implications described would follow. And in fact there are many problems about the precise status of the mindblindness hypothesis, to do with its explanatory power and specificity to the case of autism, how it interacts with the other two “fundamental deficit” theories, and, crucially, whether it can incorporate and reflect the idea of a spectrum of *developmental* abilities and impairments (Wellman et al. 2001). At present, it may be best viewed as a metaphorical description rather than an explanation of autistic behavior or as a step on the way to a full and coherent psychological explanation of autism. But even if the “mindblindness” theory is correct, neither of the claims said to follow, about the moral status of people with autism and the possibility of a flourishing autistic life, would necessarily follow. It is important to remember that the notion of a moral person at play here is highly

stipulative, a matter of moral argument and decision rather than an empirical discovery of facts about human beings. Indeed, the long history of the idea that those who are “different from us” should thereby be placed outside the circle of our moral concern or assigned a diminished level of moral status is an ignominious one. Again, accounts of a flourishing human life that assign so central a place to friendship and the emotional life may be seen as simply begging the question when it comes to people with autism. Even for non-autistic people, the need for friendship and socialization fluctuates and may be quite minimal. To assume that socialization with others is so important that we cannot have well-being without it may be to buy far too much into a contemporary culture which values extrovert behavior. Furthermore, it can be seen as dangerous, for the future if not the present. Arguing that autistic people alive today have a less flourishing life than the rest of us may be a problem for them, but its implications may be much more fateful for a future context in which emergent genetic technologies will play a major role in reproductive decisions about whether to prevent the birth of disabled individuals.

The advent of a “neurodiversity” movement led by, and giving a voice to, people on the autistic spectrum and their families and supporters has brought a sharp political edge to this ethical question of how we should value autism. Drawing on a wider political debate about disabilities and disability rights and paralleling campaigns by other disadvantaged groups to change societal perspectives of their condition, the neurodiversity movement forces attention onto the complexities and contested nature of the concept “normality,” the positive aspects of autistic spectrum conditions, and the advantages as well as the justice of respect for cognitive differences. Autism is claimed to be simply a neurologically atypical, but not abnormal, human variation. A distinction between “neurodiverse” and “neurotypical” functioning displaces the conceptually and morally problematic distinction between “normal” and “abnormal” functioning, with the implication that we should no longer think of autism as a condition requiring fundamental treatment,

correction, or prevention. Support for this stance is sometimes drawn from the list of famous people – including Isaac Newton, Albert Einstein, Carl Jung, Immanuel Kant, Vincent Van Gogh, Bill Gates, and Andy Warhol, among others – who are deemed to have had, or to have, autistic traits. Whatever their case to case legitimacy – and this may be doubted (Verhoeff 2012) – these attributions have been sufficiently plausible to contribute to a shift in the perception and representation of autism, from outright “disability” toward “difference,” while also encouraging those with autism to celebrate the distinctive strengths of their historical community. On the other hand, the neurodiversity movement’s drive to construct a specific autistic identity faces some possible social and philosophical challenges: for example, the claim that autistic people are specifically neurologically different – they are *neurodiverse* – is contentious, while there is little in the way of consensus about the etiology of autism (Ortega 2009). Similarly, the ontological claim that individuals are identical with and can be defined by their neurological traits is a claim which is currently highly contested and possibly philosophically incoherent. In any case, there is a risk to be guarded against; that emphasis on a biological basis of “difference” – a still unidentified but presumed to be “deep” basis – may inadvertently reinforce queries regarding the moral status of people with autism. There is, perhaps, such a thing as being “too different.”

On the other side of the debate about how to value autism, an equally vocal lobby regards autism as a serious disability and supports funding of the kind of scientific research that might lead to prevention and cure. These objectives are shared by many carers of autistic people and many autistic people themselves, who claim that the neurodiversity movement underestimates the grave effect autism has on the lives of everyone involved. It does not, and cannot, represent those so severely disabled by autism that they are incapable of speaking for themselves or the families and carers of those with severe cognitive impairments or even those high-functioning individuals who often experience acute isolation and loneliness. The disagreement between this group and

the neurodiversity movement is somewhat reminiscent of the conflict within feminism in the 1960s and 1970s when there was a grassroots challenge to a feminism perceived as the expression of the needs and concerns of middle class white women alone and which ignored the different difficulties faced by some women due to race, class, nationality, poverty, level of education, and religion (Crenshaw 1991). Similarly, it might be said that while an identity-based politics such as that advocated by the neurodiversity movement may be a great source of strength and community, it also runs the risk of conflating and ignoring important intragroup differences and the obstacles to be overcome because those difficulties interact in complex ways with other possible forms of oppression.

The autism research agenda is a major focus of the conflict between advocates of neurodiversity and those who view autism as a catastrophic disorder. Despite the growing influence of the neurodiversity movement, early detection, prevention, and cure still seem to be the main impetus and the overriding goals of biomedical research into autism. The National Institute of Mental Health in the United States, for example, proclaims its vision to be “a world in which mental illnesses are prevented and cured” and names autism as one of a group of “serious, often life-threatening illnesses for which we need reliable diagnostic tests, new treatments, and effective strategies for prevention” (National Institute of Mental Health [NIMH] 2008). One of the largest autism charities in the world, Autism Speaks, declares itself “dedicated to funding research into the causes, prevention, treatment and a cure for autism” and has donated more than \$160 million to such research since its inception in 2005 (Autism Speaks 2012). The official mission statements of such research agencies also include research support for those who must live with autism – and they and their supporters are not necessarily opposed to respecting cognitive difference. It remains, however, that these seem not to be their priorities. One of the main bones of contention in this area is about whether research funding should be directed toward improving the lot of autistic people living now rather than

be for the benefit of future generations of those with autism: proponents of the neurodiversity approach have little trouble suggesting research projects that would have objective practical benefit for those who live with autism, if only funds were more equitably allocated.

However, the more basic criticism from the neurodiversity perspective is that the goals of prevention, radical treatment, and cure are fundamentally misguided. The value issues here are complex. They include, but go well beyond, interpretations of the key terms. A “cure,” to start with it, ought to be rather more than something that would ameliorate the negative impacts of autism on affected individuals. But taken to mean something that “gets rid” of autism, it faces two distinguishable challenges. The first, relating to identity, is captured in a website statement of a view that is often expressed by those in the neurodiversity movement: “To ‘cure’ someone of autism would be to take away the person they are, and replace them with someone else” (Aspies for Freedom 2010). The obliteration of the condition is seen here as amounting to the destruction of an identity. That this view is persuasive owes much to two features of autism: first that by its cognitive nature, it has a pervasive impact on a person’s life and second that it is an early onset condition assumed to be a pre-experiential and pre-social “given,” though not manifesting itself in the very earliest years. In combination, these features imply that autism by its nature is truly deep set in those who have it and live with it. Whether it is constitutive of a person’s identity in the way suggested is an open and very difficult philosophical question. However, it seems pertinent to observe that identity, in one important sense, is something that is acquired, built up, and defined progressively. So, while curing, as opposed to ameliorating, an adult’s autism may be a destructive project, if indeed it is not an incoherent one, the case is less clear where infants are the likely recipients of the cure.

“Prevention,” to come to it, does not have to mean “eradication” inasmuch as its primary reference may be symptoms rather than the condition itself. So, a major goal of research programs, whether biological or psychological, may

be to identify interventions that “prevent” the more severe cognitive, behavioral, and social challenges that are often associated with autism and impact negatively on autistic individuals and their families. This prevention may be by early treatment that forestalls the significant development of these challenges or by interventions that reduce or limit their impact when they have already developed, by restoring function as much as possible. Regarding the latter, the neurodiversity lobby object to specific research and interventions aimed at “normalizing” certain autistic behaviors, such as prolonging eye contact or reducing “stimming,” where that is done for no more objectively important reason than to make the person with autism less visible by encouraging them to fit in with contemporary cultural norms.

The Future

All discussions of autism and the ethical problems it throws up suffer from the undermining effect of uncertainty about how well autism is established as a cohesive syndrome. The Medical Research Council of Great Britain puts this uncertainty this way: “Whilst it is well known that autism involves impaired social communication, language impairment, and repetitive, stereotyped interests, it is still unknown whether this constellation of impairments is inherent in a cohesive syndrome (usually called Autism Spectrum Disorder or ASD), or whether it is an artefact of diagnostic practice” (MRC 2010). Some scientists have suggested that autism is not a single large spectrum of disease but that what we call autism is in fact a group of conditions with multiple etiologies (Coleman and Gillberg 2012). Yet others question whether there is such a thing as autism in the natural biological world (Timimi et al. 2011) or draw attention to the way autism has emerged and developed in close relation to historical and social ideas about what constitutes acceptable and abnormal behavior (Nadeson 2005). The lack of a clear scientific, medical, and public consensus on the definition, causes, diagnosis, and treatment of autism means that many ethical issues pertaining to autism are probably

still to emerge. No doubt this process cannot be hurried given that it depends on future scientific and medical developments, on an array of social, cultural, philosophical, and psychological issues and crucially on the involvement of the autistic community. Two issues of current ethical importance are identified here.

The first concerns the area of intelligence testing in autism. The history of intelligence testing is, on the whole, an ignominious one in which many historical examples illustrate the fact that IQ tests merely confirm the existence of well-known social disadvantage (Gould 1996; Hayman 2000). It is said that most children with autism exhibit mild to moderate cognitive deficits with a characteristically uneven cognitive profile, though the rates of intellectual disability in autism range widely between 40% and 63% (Matson et al. 2008). One question that arises then concerns the precise relationship between autism and IQ levels: does level of IQ affect the range and expression of autism symptoms? Of more basic concern is the effect of mainstream deficit approaches to autism on our understanding and conceptualization of autistic intelligence. We have seen how these approaches may be criticized for the personal and social harm they effect. But is it also possible that they impede scientific and philosophical progress in understanding intelligence in autism? In general, IQ testing in autism is carried out in a way that shows little evidence of the much wider social debate about the general validity of IQ testing and what it tests, the equation of intelligence with IQ, and the existence of different sorts of intelligence (Gardner 1983). This narrow frame of reference combined with a deficit approach to autism not only determines what is researched but may also affect test results. For example, it seems many cognitive scientists fail to appreciate how the behavioral and communication difficulties associated with autism negatively affect test performance and need not denote lower intelligence despite low scores. And in viewing autism purely as a disabling condition, they may also not recognize that to describe and measure a possibly different cognitive style with tests designed to test what is

“normal” cognition will yield results of questionable validity (Eagle 2002). The interpretation of results may also display a research bias introduced by the deficit model – when intelligence and talent are recognized, they are usually pathologized as “splinter skills” or “islets of ability,” and it has been shown that in tests where an autistic group outperforms the non-clinical control group, the difference is often explained not by superior ability in that area but by reference to some cognitive impairment associated with autism. It is clear that how we represent people to ourselves and to others often determines the outcomes of our ethical judgments about them. But the consequences of a purely deficit account of autism may also be serious and far-reaching for social justice and possibly for science itself.

A second issue probably causes most consternation in many parts of the autism community, as well as being a concern to others. It is the prospect of a future range of genetic technologies capable of indicating levels of risk of autism for the use in the context of reproductive decision-making. If and when they are developed, the availability of such technologies, it is feared, will lead to an avoidance of having children by those identified as at risk of conceiving autistic offspring and, beyond that, to large-scale elective abortion of fetuses deemed to be at some – perhaps even quite small – level of risk.

Supporting the fears of proponents of neurodiversity about an agenda to eradicate autism, there is evidence to suggest that preventing the birth of individuals with disabilities that can be diagnosed prenatally seems to many an obvious step to take and is encouraged by medical professionals and bioethicists alike. Some bioethicists have even argued that there is a moral obligation to prevent the births of disabled individuals where possible and regardless of the level and kind of disability (Savulescu and Kahane 2009). As their decision-making is likely to be influenced by available genetic information, it will be important to offer parents counseling about genetic and non-genetic risk factors; potential social, educational, and developmental outcomes; and treatment options (Walsh et al. 2011). It will also be crucial

precisely how genetic counselors communicate the probabilistic and uncertain picture derived from genetics as well as the complex and contested nature of the autistic spectrum itself, since this is also likely to have a huge impact on what parents decide. From a moral point of view, this is an extremely important issue for genetic counselors and society at large, for it has been suggested that even if individual parental decisions in this area are not eugenic, *the choices on offer* may be regarded as such (Sparrow 2008).

Professional guidelines for genetic counselors display a strong commitment to patient autonomy particularly in regard to reproductive decisions because of a belief that parents are in the best position to know what they should do and have a right to choose (and also, no doubt, to distance the practice of genetic counseling from questions of eugenics and the promotion of abortion). Many would agree that the final moral decision appropriately lies with the choosers among the available options – that is, the parents of the actual or potential child at risk of autism – with the hope that important ethical considerations regarding, for example, the morality of abortion or how we should think about disability and disabled lives would continue to weigh heavily in the choices people make. Even this seemingly moderate point of view may be challenged however. It could be argued that just as our autonomous decisions affecting others including our children after birth are restricted by considerations of harm to others, so should they be similarly restricted before birth. Should parents decide to abort a fetus identified as at risk for autism (if and when that becomes possible), their choice, it may be claimed, harms the fetus in that from the fetus' point of view, it is better to be born autistic than not born at all. Hence the harm criterion suggests abortion in such cases is wrong (Barnbaum 2008). It is unclear whether proponents of this view think abortion is wrong in all circumstances, wrong in all cases of disability, or wrong because it is the abortion of people with autism. However, if living an autistic life is less good than living a non-autistic life, considerations of harm would not serve to restrict those parental choices aimed at preventing the existence of autistic children (e.g.,

through preimplantation genetic diagnosis). What this brief discussion of the complexity of reproductive decision-making as it pertains to autism again indicates is how necessary it has become to think about how autism is and should be characterized: it seems winning the battle of words about the value of autism is not only important for setting and reorienting the research agenda but is likely to be crucial in life and death decision-making in the context of future reproductive choices.

Ethiopia and Autism

Sebiha M. Abdullahi

Child Study Center, Yale University, New Haven, CT, USA

Historical Background

Historic, Economic, and Cultural History of Ethiopia

Ethiopia is a country located in the Horn of Africa rich in archeological, historical, and cultural heritage. Archeological findings have mapped Ethiopia as the birthplace for humans, *Homo sapiens* (McDougall et al. 2005). Lucy, a hominin who lived 3.2 million years ago was discovered in 1974 in the Awash Valley, Ethiopia (Johanson and White 1979). Ethiopia also has the highest number of UNESCO World Heritage Sites in Africa reflecting the role the region played in ancient and modern civilizations. Axum (monolithic obelisks), Fasil Ghebbi (palaces of Ethiopian sixteenth and seventeenth century emperors), Harar Jugol (walled historic city), and Konso cultural landscape and Lalibela (rock-hewn churches) (Ethiopia 2016a) are a few of the many sites. Ethiopia is also home to natural wonders like the Ethiopian Highlands, the Roof of Africa that form the largest continuous mountain through which the Blue Nile courses (Henze 2000). These mountains are inhabited by endemic animals like the gelada baboon, walia ibex, and the Ethiopian Simien fox. On the south-eastern part of the country in the Oromia region lies the Sof Omar Cave, which is the largest system of caves in Africa (Robson 1967).

In addition to its historical heritage, Ethiopia is notable for its strong resistance against Italian occupation that was used as a model for anti-colonial resistance across the continent. Ethiopia was in the forefront during the formation of Organization of African Unity that is now African Union (El-Ayouty and Zartman 1984). Addis Ababa, Ethiopia's capital city continues to be the center for African peace and development efforts as it serves as the headquarters of United Nations

Economic Commission for Africa, the African Union, and the Pan African Chamber of Commerce and Industry.

Ethiopia has one of the fastest growing economy in Africa with a GDP per capita of \$1800 (Ethiopia 2016b). Ethiopia has a population of approximately 100 million people (Ethiopia 2016b). Eighty percent of the population lives in rural areas primarily engaged in agriculture. Ethiopia's very diverse population comprises of more than 80 ethnic groups. There are about 88 individual languages spoken in Ethiopia. Amharic is the official national language and has its own unique script that grew out of the Ge'ez, ancient liturgical language (Roncovic 2005). Oromo, most widely spoken language in Ethiopia, Somali, Tigrigna, and Afar are regional official working languages (Ethiopia 2016b). English is the major foreign language taught in schools and universities (Ethiopia 2016b). Several sign languages that are derived from signed Amharic and English languages are primarily used in schools for those with hearing disabilities throughout the nation (Morgan 2009).

Education in Ethiopia

Traditional education and literacy associated with the Coptic Church and mosques in Ethiopia dates back over 1000 years (Ridley and Bridges 1998). Western style education was introduced to Ethiopia in 1908 (Tessema 2007). Despite a long history of education in the country, the literacy rate in Ethiopia is still low at 49.1% as of July 2016 (Ethiopia 2016b). The low literacy is partially due strain on the availability and access to resources by the rapid rise in population and increasing burden of those under the age of 15 which currently accounts for about 40% of the total population (Ethiopia 2016b). In fact, in many areas, the student to teacher ratio can be greater than 40:1. In addition to the teacher shortage, another obstacle for early education in Ethiopia is the lack of training in education; indeed, only 48% of primary school teachers are trained (Education for All: Global Monitoring Report 2014).

Furthermore, not only is primary education sparse and of poor quality, but special needs

education is also practically nonexistent. Out of 285 schools with special needs classes, none were autism specific and they were evaluated and deemed between very poor and satisfactory by the Federal Ministry of Education (Burton 2016). There are no school programs specifically designed for children with autism within public schools. Hence, children with developmental disorders and disabilities are often confined to staying at home. In fact, it is estimated that only 4% of children with special needs receive primary schooling (Burton 2016).

Mental Health in Ethiopia

Research about and services available for mental health in Ethiopia is very scarce. Only 1.7% of the national health expenditure in Ethiopia was spent on mental health (Russo 2007). Amanuel Hospital is the only psychiatric hospital in Ethiopia. Mental health services and human rights issues are not regulated by external reviewing committees and Amanuel Hospital itself serves as both a service provider and a regulator of its services. There are 53 outpatient and 6 inpatient psychiatric facilities around the country, and they lack specific programs for children and adolescents (WHO-AIMS Report on Mental Health System in Ethiopia 2006). As of 2007, there were only 17 psychiatrists (all of whom work in the capital city, Addis Ababa) and 190 psychiatric nurses in the entire country (Russo 2007).

During medical training education in Ethiopia, medical students spend only 2% of their curriculum learning about mental health issues and how to manage them (WHO-AIMS Report on Mental Health System in Ethiopia 2006). In terms of physicians, all primary care physicians are able to prescribe psychotropic medicines without restrictions in Ethiopia (WHO-AIMS Report on Mental Health System in Ethiopia 2006).

Autism in Ethiopia

Autism and other neurodevelopmental disorders in Ethiopia are largely viewed as a curse. Children with these disorders are often hidden from the society. In addition to the lack of special services for them, their isolation often lead to their poor

health and nutrition. It is estimated that about 500,000 children with autism live in Ethiopia (Burton 2016). Research and services for mental health have focused on severe mental disorder disorders so far (Burton 2016). National Mental Health Strategy has started an initiative to educate primary health-care workers about mental health disorders but neurodevelopmental disorders have yet to be included in the training (Burton 2016). In the two child and adolescent psychiatric clinics in Ethiopia, neurodevelopmental disorders are the second leading cases after epilepsy (Burton 2016).

Legal Issues, Mandates for Service

Various national and international initiatives have been underway in the past two decades to improve the services for those with mental health problems and disabilities. In accordance with the UN Convention on the Rights of Persons with Disabilities, the National Plan of Action for Inclusion of Persons with Disabilities 2010–2020 was designed and finalized in 2011 to grant equal rights to people with disability and ameliorate their standard of living in Ethiopia (WHO-AIMS Report on Mental Health System in Ethiopia 2006). In addition, to improve the quality and the availability of primary education in Ethiopia, United Nations Educational, Scientific and Cultural Organization (UNESCO) has made a five-year plan to train about 6000 well-qualified teachers, 155 of which would be trained in special needs education (WHO-AIMS Report on Mental Health System in Ethiopia 2006). World Health Organization Mental Health Gap Action Program (WHO mhGAP) is also preparing a parent training program for those with children with neurodevelopmental disorders to address the misunderstandings about the disorders and help them interact with and manage challenging behaviors of their children (Burton 2016).

Health Education and Training + (HEAT+) project that was launched in 2012 is primarily aimed at helping health workers to be able to identify neurodevelopmental disorders in the field (Burton 2016). Health extension workers,

who provide health education about topics like hygiene and contraception, are being trained to detect and support those with mental health conditions by the Ethiopian Federal Ministries of health and Education and the Open University (UK) (Burton 2016).

Overview of Current Treatments and Centers

The Nia Foundation's Joy Center was founded by Zemi Yenus in 2003. She opened the school after seeing how schools were unwilling to accept her son with autism. Now the center provides services for about 80 children and offers diagnosis and assessment for autism (Burton 2016). Ms. Yenus has been in the forefront of campaigns to spread awareness about autism.

Nehemiah Autism Center was established in 2010 by ReachAnother Foundation and Rahel Abayneh in Addis Ababa. ReachAnother Foundation, founded by Dr. Marinus Koning, is a US based, nonprofit organization that aims to improve healthcare and special education services in underserved populations in Ethiopia. Ms. Abayneh like Ms. Yenus was determined to open an autism center because she could not find services for her son with autism. When the center was first opened, its teachers were previous kindergarten teachers, parent volunteers of children with autism, and psychology graduates from Addis Ababa University. The center primarily uses principles of Applied Behavior Analysis (ABA) on the children attending the center. Currently, 60 children receive services at Nehemiah.

The Bethel Adama Center for Autism was established in 2015 in Adama in the Oromiya region by the ReachAnother Foundation. It is the first center established outside the capital city and it currently has four teachers who provide services to 20 children.

The Bright Autism Center was recently established in May of 2016 in Hawassa, in the Southern Nations, Nationalities and Peoples' region of Ethiopia also by ReachAnother Foundation. The center closely collaborates with the

Hawassa University Psychology Department and University of Dilla Special Education Department to train teachers and spread awareness about autism in the local community.

Overview of Research Directions

Given that autism has only recently garnered attention, not much research has been conducted about autism in Ethiopia. In fact, the first autism-related research project was conducted as part of the Health Education and Training + (HEAT+) project. The study showed the limited amount of diagnostic and education services for children with autism in Ethiopia (Tekola et al. 2016). The prevalence of neurodevelopmental disorders, the clinical manifestation of autism in this subset of population, and the effectiveness and the application of autism diagnosis and treatment methods within the context of Ethiopia are yet to be studied.

Overview of Training

The four autism centers have not only been sources of services for children with autism and other neurodevelopmental disorders but also have been critical in autism training in Ethiopia. Professionals through the ReachAnother Foundation and Addis Ababa University Psychology Departments make visits to these centers and train the teachers in speech pathology, occupation therapy, and ABA therapy.

²Yale Child Study Center, School of Medicine, Yale University, New Haven, CT, USA

Definition

The University of Bath Autism Summer School (UBASS) is a university transition program that introduces autistic students to life at university through the lens of work, rest, and play. The program aims to help students make a more informed decision when selecting and applying to universities in the UK.

Historical Background

Autism at University

In recent years, there has been an increase in autistic students' participation in postsecondary education. For example, in the UK, the widening participation agenda set up by the government aims to increase accessibility to postsecondary education for students from more disadvantaged backgrounds, as well as students with physical disabilities and other forms of developmental and specific learning disabilities, and has helped increase participation rate in higher education for autistic students from 7.4% in 2009/2010 to 10.7% in 2014/2015 (Connell-Smith and Hubble 2018). However, despite an overall increased participation rate, the transition to university can be an especially turbulent process for many autistic students.

Previous studies that have investigated students' mental health and well-being at university have found that up to 71% of autistic students reported symptoms of anxiety, 53% reported

loneliness, and 47% reported experiencing symptoms of depression (Gelbar et al. 2014), as well as increased rates of suicidal ideation and attempts (Jackson et al. 2018a). In the USA, it is estimated that only 35% of autistic students can complete their postsecondary education, which is lower than 38% of graduation rate for students with other disabilities and 51% of typically developing peers (Fisher and Hood 1987). Similarly, in the UK, fewer autistic students graduated from university with 2:1 or first-class honors degree (62.8%) compared to students with other forms of disabilities (66%) and typically developing peers (68.1%) (Lucas and James 2018). Furthermore, for many autistic students, university does not necessarily guarantee a safe passageway to employment following graduation. In the UK, within 6 months of completing their degree, autistic students are more than twice (18.5%) as likely to be unemployed compared to students with other disabilities (7.2%) and almost four times as likely to be unemployed compared to their typically developing peers (5.1%) (AGCAS Disability Task Group 2014).

With a growing number of autistic students facing the potential transition to postsecondary education, it is important for university stakeholders and transition services to provide informational, practical, and emotional support during the transition process to both the students and their family/caregivers and help make an informed decision as to whether or not university may be the right choice for each young person in question. In addition, the poor retention, graduation, and employment prospects for autistic students transitioning to university have called for more research to better understand the challenges associated with transitioning to postsecondary education (Jackson et al. 2018b), in order to facilitate universities and transition services to develop support plans and interventions to address students' unique needs and vulnerabilities when transitioning to university.

Understanding Students' Strengths and Vulnerabilities

Compared to their peers, autistic students often struggle in the complex university social setting. Although having poor social communication

skills is one of the core diagnostic criteria of autism spectrum disorder (ASD) (American Psychiatric Association 2013), many autistic adults and young people also experience co-occurring anxiety, with a lifetime prevalence rate for any disorders being between 27% and 79% (Hollocks et al. 2019; Kent and Simonoff 2017), as well as elevated rates of social anxiety, marked by having a persistent fear of being in one or more social situations that can lead to increased social avoidance (American Psychiatric Association 2013). Therefore, many autistic students may be less successful in developing a new social network at university and making friends, due to compounded social communication difficulties as a result of both autism and social anxiety (Adreon and Durocher 2007; Dipeolu et al. 2014).

Many autistic students also have restricted interests and preference for routine that make them less capable of adapting to changes in schedule when transitioning to university, resulting in additional distress (Dipeolu et al. 2014). In addition, many autistic individuals experience deficits in executive functioning skills (such as planning, organization, and working memory), which is associated with poor adaptive functioning, accounting for one's ability to initiate a range of activities essential for independent living ranging from socialization and communication skills such as initiating social contact with others to daily practical living such as cooking, self-care, and time and finance management (Pugliese et al. 2015; Sparrow et al. 2005). Furthermore, many students also experience sensory difficulties such as hypersensitivity to light and noise at university (Longtin 2014), and around 31% of autistic students have reported that their transition plans and accommodations at university have failed to address their sensory needs sufficiently (Sarrett 2018).

Another issue for many autistic students to consider when transitioning to university is related to diagnosis disclosure (Adreon and Durocher 2007). As students leave their supportive family environment when transitioning to university, learning to self-advocate can be very important for securing necessary resources and support services on campus to facilitate their independent living on campus (Giarelli and Fisher 2013). In addition, typically developing students

often show increased acceptance and perceived many socially awkward behaviors displayed by autistic students more positively when made aware of the other's autism diagnosis (Matthews et al. 2015), further highlighting possible social benefits of diagnosis disclosure among peers.

Finally, in contrast to many challenges in the social and daily living domain faced by autistic students at university, academic studies can often be an area of relative strength (Anderson et al. 2018; Geller and Greenberg 2009; Jackson et al. 2018a). University often provides autistic students with an opportunity to focus on their area of special interest, for which they often display a greater depth of knowledge compared to their typically developing peers (Geller and Greenberg 2009). Autistic students often also demonstrate more systematic way of thinking that is more logical and rational compared to their typically developing peers (Baron-Cohen et al. 2009), as well as paying more attention to detail (Happé 1997), which can be advantageous in subjects in the fields of science, technology, engineering, and mathematics (STEM). Helping autistic students to better recognize and utilize their strengths at university can help them become highly skilled professionals in these disciplines, which are particularly attractive for many employers in finance, engineering, and scientific industries and thus help increase their employment rate following graduation (Shattuck et al. 2012).

Interventions Supporting Student Transition to University

To date, interventions aimed at supporting autistic students to transition to university have largely included contacts (e.g., Shmulsky et al. 2015) and campus-based events that help provide information for students considering and seeking to apply to university (e.g., Retherford and Schreiber 2015) and peer support during early stages of the actual transition (e.g., Littlefield 2010). The content for the majority of pre-transitional programs are developed to address autistic students' concerns identified through qualitative studies, such as meeting coursework requirements, disability awareness on campus, social skills and social relationships, availability of practical and emotional support, organizational difficulties such as

time management and problem-solving skills, sensory challenges, and mental health concerns (Cai and Richdale 2016; Camarena and Sarigiani 2009; Mitchell and Beresford 2014; Van Hees et al. 2015; White et al. 2016).

Participation rate in postsecondary education for students who have either actively taken part in transition planning (61%), as well as those who have received instruction specifically focused on transition planning (74%), is almost two to three times greater compared to students who did not participate in transition planning (36%) or receive transition-planning instructions (24%) (Chiang et al. 2012; Wei et al. 2016), thus highlighting the importance of pre-transitional planning to increase higher education accessibility among autistic students.

In addition to increasing participation rates, developing a well-informed and useful pre-transition package to aid autistic students transitioning to university should also (1) serve as a platform for offering insights into university life to help autistic students make a more informed decision regarding university and (2) help students recognize their support needs which can be communicated to the relevant stakeholders and transition services and to help develop more personalized support plan for transitioning to university. The University of Bath Autism Summer School (UBASS) is an annual pre-transitional residential program running since 2012 that emphasizes on helping autistic students experience firsthand what university life is like, through various sessions structured around the themes of “work,” “rest,” and “play.” A summary of the UBASS program, as well as students’ feedback and evaluation from the first 5 years (2013–2017), has been published (Lei et al. 2018) and is summarized below, with future directions for research and practice highlighted.

Current Knowledge

University of Bath Autism Summer School (UBASS) Program

The Autism Summer School program is delivered across 3 days on a campus-based university, including two overnight stays in student

accommodation on campus. Students aged 16+ who hold a diagnosis of autism from a clinical professional seeking to learn more about university are eligible to apply using the online application system. Each year, around 20–30 students attend the Autism Summer School. Prior to arrival at the summer school, students are contacted and asked to complete some questionnaires surrounding their worries and concerns associated with transitioning to university, self-report levels of social anxiety, as well as self-reports on their social communication skills and level of autism identity. Parents are also contacted regarding students’ medical information, as well as additional dietary and other requirements. The questionnaires collected inform the program administrators to make reasonable adjustments for the students prior to their arrival. The summer school curriculum is developed to introduce students to sample different aspects of typical university life through the lens of “work,” “rest,” and “play” and to help promote self-care and well-being when at university. All sessions are delivered face-to-face in a group setting, with varying group sizes depending on nature of the session. A more detailed description of the sessions offered under each theme is shown in Table 1.

With the exception of two, all remaining sessions are prepared and delivered by academic and clinical staff in the Department of Psychology or staff from the disability and careers service at the campus university, who all have extensive experience working with autistic students at university. The two remaining sessions include (1) employment session delivered by an external employer who have an autism at work program and informs students about potential internship and career development opportunities alongside their studies, as well as what adjustments students can request to facilitate their application process, and (2) experience at university session delivered by autistic students who are either currently at or have recently graduated from either undergraduate or graduate studies. Clinical psychologists (both licensed and in training) delivered the anxiety-related psychoeducation sessions.

Beyond the structured timetabled sessions, many structured and unstructured social opportunities were also embedded into the program, to

Evaluation of a Transition to University Program for Students with Autism Spectrum Disorder,
Table 1 Description of sessions offered at University of Bath Autism Summer School

Session	Description
Work	
Sample lecture	Experience teaching in lecture style, delivered in a lecture theater
Social and cultural aspects of student life	Learning more individual differences at university and adapting to a more socially and culturally diverse environment
Employment after university	Delivered by employer – focusing on how to navigate internship and seeking adjustments during application process. Careers service offers guidance on careers support on campus
Playing to the academic strengths associated with ASD	Understanding personal strengths associated with autism and how to best use them to improve academic studies and beyond
Rest	
Managing stress and anxiety	Psychoeducation session on how to identify stress and anxiety, adaptive coping mechanisms, and how to seek support
Social relationships	Addendum to psychoeducation session on managing stress and anxiety, with a more specific focus on managing social anxiety
Talking about your diagnosis	Workshop on understanding the pros and cons associated with disclosing diagnosis on campus, focusing on when best to disclose, who to disclose to, and how to disclose
General living and eating on campus (throughout the 3-day experience)	Experience firsthand what student accommodation is like and how to find and order food on campus
Play	
Speakers with ASD: An insider's view. Student support at university and beyond	Current autistic students and/or recent graduates sharing their personal experience of university life, as well as tips and advice
Clubs and societies at university	Showcasing how to enrich social life on campus through joining/starting a club or society of relevant interest
Sports and activities	Trialling out sport facilities on campus for leisure use
Visit town center and historical site of interest	Exploring life outside of university campus, informal socializing opportunity, and practice travelling to and from campus

help students overcome some of their social challenges and to help facilitate students to both initiate and take part in socializing with both typically developing students (the student ambassadors), other autistic peers, as well as faculty staff. To ensure students fully experience living on campus, during the summer school, all students stay in student accommodation on campus, which are single en suite bedrooms that are housed together in small flats, with six to seven people staying in each flat, which has a shared communal and kitchen area. Students also have catering and dine on campus for all of their meals, including ordering food for dinner from the student canteen. Throughout the summer school, students are also supported by “student ambassadors” who are current students at University of Bath trained to support widening participation and inclusion

activities on campus. In addition, a group of overnight supervisors who are either undergraduate or graduate students also stay in student accommodation along with students every evening and help address any issues that might emerge overnight. All student ambassadors and overnight supervisors have received a specific training session prior to the summer school to become more familiar with the needs of autistic students.

Feedback and Evaluation

Every year, students are asked to provide feedback evaluating their experience at the summer school, to help administrators review the sessions offered and amend the curriculum to best address students' needs based on feedback. Students' evaluation across the first 5 years of the program (2013–2017) was collected using mixed methods,

which focused on (1) changes in short-term outcomes in respect to worries and concerns about attending university; (2) student satisfaction ratings with the overall program; and (3) qualitative written feedback about the summer school. Overall, a total of 122 participants aged 16–30 years (mean age = 17.76 years) took part in the summer school from 2013 to 2017, 91 students were male (74%) and largely Caucasian (90.1%).

Following completion of the summer school program, students from 2013 to 2017 reported significant reductions in their worries and concerns associated with various aspects of transitioning to university, including navigating the social world, coping with leaving home, and meeting academic demands, daily living skills, and time management. The reduction in worries and concerns associated with a broad range of topics highlights that the Autism Summer School program was effective in improving students' understanding and perception of different aspects of university life. Students also rated the summer school to be very enjoyable and helpful, and the majority also viewed going to university more positively. Students were also asked to give qualitative feedback on what they found to be the most helpful at the Autism Summer School, as well as what they were most looking forward to about going to university.

Students found that both the content and delivery format of many of the lecture sessions were very helpful, including a range of topics such as psychoeducation about managing stress and anxiety, how to best utilize their strengths at university, hearing experiences of past autistic students, and the importance of diagnosis disclosure and accessing support at university, as well as learning more about clubs and societies. Some students also highlighted the usefulness of finding out more about university life firsthand, such as staying in university accommodation, eating in canteens, and visiting the university campus as well as seeing different departments related to their subject of interest. Finally, some students also commented on enjoying the chance to meet and socialize with other autistic students, as well as student ambassadors, which have helped to relieve some of their anxiety

around socializing with same-aged peers in a university setting.

The majority of students also gave a more positive outlook when asked about what they were most looking forward to about going to university, especially about having new social opportunities and meeting similar-minded people through their academic studies, accommodation, and joining new clubs and societies. A few students also commented on looking forward to meeting other autistic students at university, as well as making friends with other students during the summer school who will be attending the same university as themselves. Students were looking forward to the many new experiences that university life will bring, and that the summer school has helped eased some of their transition worries, though not all. Some students were particularly looking forward to the prospect of pursuing their academic subject at university to greater depth and their desire to perform well academically. Some students commented on looking forward to having greater independence at university and becoming more confident with greater range of social experiences, as well as looking forward to having their own routine and personal space at university. A few students commented on how the summer school has helped them recognize how to access support at university and from whom and the need to actively seek out help when needed. Finally, a few students commented on how the summer school has helped them make a more informed decision about whether university may be the right choice for them, and that they will be rethinking their university application, and possibly delaying entry until they felt ready to begin.

Future Directions

The University of Bath Autism Summer School (UBASS) provides an example of a pre-transitional program that helps autistic students to gain more first-person insights into life at university and has been shown to help students feel less worried and have a more positive outlook about starting university upon completion. The

social, nonsocial, and anxiety-related concerns raised by autistic students prior to transitioning to university can thus be addressed in a manner that is perceived to be helpful and enjoyable and serve as an important stepping stone for those who are seeking to apply, or transition, to university. However, one key limitation of the evaluation is that only short-term (i.e., immediately after completing the summer school) outcomes were evaluated, and no long-term impacts have been assessed, such as students' participation rate in postsecondary education following the summer school and transition outcomes. Using a longitudinal design with continued evaluation of transition to university experience for autistic students who have attended the summer school (or another pre-transition program) versus those who did not can further help evaluation of the summer school program and ask students to reflect in hindsight what they would have liked the summer school to include to facilitate their transition.

Overall, university stakeholders and transition services are recommended to offer more tailored support to autistic students who are transitioning into, through, and out of university life. Using the UBASS example, offering a structured pre-transition program that embed key components relating to daily life on campus such as staying in university accommodation as well as ordering food from the cafeteria can alleviate some of the worries autistic students have prior to applying to university (Lambe et al. 2018). Actively including the autistic students, as well as having clear communications between stakeholders and caregivers and family members to begin the university transition planning early, can give students the opportunity to have enough time to reflect on what their strengths and weaknesses are and to identify their personal support needs. It is also important that families and students are made aware of other alternatives beyond that of university studies and postsecondary education, as well as the possible career prospects following university studies, so that an informed decision can be made in the best interest of the young person in question. To support autistic students transitioning through university, ongoing support in the domains of socialization (e.g., autism social groups), as well

as daily living and academic studies (e.g., such as having a designated peer mentor or support buddy), should be carefully considered, and students should be made aware of the resources available to them. Furthermore, increasing autism awareness and training for both school teachers and university staff can also be important. Ensuring that school teachers are made aware of the support needs of autistic students and the importance of helping students decide when and how to disclose their diagnosis to seek the support they need when applying to university can help secure resources earlier on in the application process. Helping university staff to better understand autistic students' strengths and weaknesses, and in particular on how to tailor teaching and coursework assignments to help autistic students better utilize their strengths, can further help students realize their full potential at university. Finally, helping autistic students to start preparing for transitioning out of university and seeking employment earlier on during their university studies can also improve their postgraduation prospects. Educating students about the employment application process, such as how to seek adaptations from employers based on their needs and having more tailored interview skills training, can help students ease some of their worries associated with job seeking and help students better use resources available to them on campus to secure future employment.

Synonyms

ESP

Definition

In 2000, Diane Parham and Cheryl Ecker formally shared their work called the *Evaluation of Sensory Processing* (ESP). This parent questionnaire, whose development was originally initiated by LaCroix in 1993, was intended to identify behaviors thought to be indicative of sensory processing problems. The unpublished test, produced at the University of Southern California, was ultimately included in the 2002 (Parham and Ecker 2002) text titled *Sensory Integration: Theory and Practice* (2nd ed.) for occupational therapy clinician's to utilize in practice. After many years of research on the utility of the tool, the authors signed an agreement with Western Psychological Services (WPS) to complete the standardization and normative sampling. Simultaneously, WPS was also working with a group of researchers currently undertaking the task of developing a similar testing instrument for use within the school environment called the *School Assessment of Sensory Integration* (SASI; Miller Kuhaneck, Henry, & Glennon, unpublished). The two assessment tools, one for parents and one for educational staff, were ultimately combined for standardization to create the *Sensory Processing Measure* (Parham et al. 2007) and the *Sensory Processing Measure - Preschool* (Miller Kuhaneck et al. 2010).

Event-Related Functional Magnetic Resonance Imaging (fMRI)

Kevin A. Pelphrey Harris
Child Study Center, Yale University School of Medicine, New Haven, CT, USA

Synonyms

[Blood-oxygen-level-dependent \(BOLD\) contrast; fMRI; Functional MRI](#)

Definition

Functional magnetic resonance imaging (fMRI) is a brain imaging technique that uses a standard magnetic resonance imaging scanner, a high rate of image acquisition, and specialized pulse sequences to measure localized brain activity. In

most cases, fMRI takes advantage of the endogenous blood-oxygen-level-dependent (BOLD) contrast to image brain activity without the use of ionizing radiation. As such, this technique is ideal for studying the developing brain in children. The technique is now the dominant technique for the study of brain function and its disruption in autism.

Psychiatry and Behavioral Sciences, UW Autism Center, University of Washington, Seattle, WA, USA

Synonyms

[Evoked potentials](#)

Definition

An event-related potential is an electrical brain response, recorded via electroencephalography,

time-locked to a particular stimulus or event. External visual and auditory stimuli are commonly used in ERP research. In order to isolate the response to the particular stimulus being studied, multiple trials of responses to similar stimuli are averaged together to produce a composite waveform, ultimately reducing the potential influence of extraneous factors.

Exceptionality

Michael Miklos
Pennsylvania Training and Technical Assistance
Network, Harrisburg, PA, USA

Synonyms

[Abnormality](#); [Atypical](#); [Disability](#); [Extraordinary](#)

Definition

Having some degree of difference from an established norm in a specific skill area. Exceptionalities may include characteristics including disabilities as well as special gifts and talents. An individual with a noted exceptionality may present a need for special education or supports in relation to a disabling condition or due to special talents or abilities such as mental giftedness. Individuals with autism spectrum disorder may present

exceptionalities that are below what would be normally expected in some areas of function and may also present exceptional abilities above the norm in others. The term “exceptionality” is often used interchangeably with the terms “disability” and “special need.” Many state statutes use the term “exceptionality” to denote categories of disability. Autism is one example of a category of exceptionality.

Executive Function (EF)

Marjorie Solomon
Department of Psychiatry and Behavioral
Sciences, UC Davis M.I.N.D. Institute,
Sacramento, CA, USA

Definition

“Executive functions” is a broad term used to describe the set of cognitive processes required to prepare for and execute goal-directed behaviors. Various theoretical models propose that executive functions are executed by slightly different component processes. However, in general terms, these components are thought to include:

- Goal (or rule) representation, which also may be referred to as working memory
- Inhibition

- Cognitive flexibility, which also may be referred to as set shifting or task switching
- Planning

Some also consider “higher level” cognitive processes like problem solving and abstract reasoning to be forms of executive functioning. Other terms such as controlled (versus automatic) processing; selective attention; and supervisory attention, which originate in different theoretical models, may be used to describe the properties of executive functions.

Historical Background

Impairments in executive functions are among the most consistently reported deficits in individuals with autism spectrum disorders or “ASD” (see Hill 2004; Ozonoff et al. 2006; Pennington and Ozonoff 1996). Many early studies of executive functions in autism used the Wisconsin Card Sorting Test (WCST), which requires participants to figure out a sorting rule, derived from one of the cards’ three dimensions (color, quantity, or design), based on minimal feedback. Once the participant has demonstrated that they understand the sorting rule by executing it properly multiple times, the rule unexpectedly changes. Studies using the WCST find that persons with autism tend to perseverate on incorrect responses (i.e., are unable to stop sorting using the old rule when it is no longer correct) more than matched controls. Interestingly, these impairments appear to be reduced when the task is administered on a computer.

Given that patients with focal frontal lobe lesions have difficulty in planning future actions and in inhibiting habitual responses, executive functions traditionally are associated with the pre-frontal cortex (PFC). Many clinical neuropsychology assessment batteries and tasks like the WCST are premised on this assumption and are designed to test what are believed to be the specific components of executive functioning based on studies of patients with brain lesions. However, more contemporary research suggests that executive

functions cannot be localized to one brain region or process.

Executive functions deficits are not specific to autism spectrum disorders. They are present in many other forms of developmental psychopathology including attention deficit hyperactivity disorder (ADHD). However, it is important to study executive functions in persons with ASD because longitudinal studies show that executive functions deficits have a parallel influence across social, language, and other domains of functioning. Furthermore, they are related to cognitive abilities that have a very strong relationship with long-term outcomes, and can serve as a treatment target.

Current Knowledge

Consistent with findings about perseveration on the WCST in persons with ASD, the most common perspective on executive functions deficits is that they are related to cognitive flexibility. More specifically, many studies have shown that individuals with ASDs have difficulty in shifting their frame of reference in thinking about problems (shifting cognitive set); in shifting how they conceptualize options that are not presented in the immediate environment (extra-dimensional set shifting); in shifting the focus of their visual attention; in shifting their attention between sensory modalities, like seeing and hearing; and in shifting between sets of rules they have learned.

Another component of executive function that is consistently found to be impaired is planning. This commonly is measured using the Tower of Hanoi or the Tower of London tasks which require participants to move disks of various sizes across three pegs. They are given a starting position and a picture of an ending position and must reproduce the ending position using the fewest moves. The task grows progressively harder over trials, and task rules prevent self-correction. The Tower task requires that the participants think through (or plan) disk moves in their heads before executing them. This is a relatively difficult task, and some have criticized the use of this type of task because it is unclear exactly what it assesses.

Several executive functions are thought to be intact in ASDs. The first of these is inhibition, which once was thought to differentiate persons with ASDs from those with ADHD. However, a growing body of research suggests that individuals with ASDs also have difficulty inhibiting prepotent response tendencies. It is unclear why there has been this shift in the literature. Some have suggested that there have been changes in diagnostic conventions since the early 1990s and that individuals formerly diagnosed with ADHD now are diagnosed with ASDs – a trend referred to as diagnostic substitution. Another possibility is that tasks that have been used to assess inhibition are not directly comparable and that generally harder tasks produce greater deficits. A second executive function traditionally thought to be intact is working memory. Here too, results have become less clear as various versions of the task have been used.

Following one study that showed that high functioning persons with autism perform better on the intelligence tests that involve more visuospatial versus verbal reasoning – the Raven's Progressive Matrices test (Dawson et al. 2007), there now have been several that show that aspects of conditional and analogical reasoning are relatively preserved in persons with ASDs.

As all parents and clinicians know, the contention that executive functions deficits create problems for persons with ASDs in everyday life would appear to be true. Individuals with ASDs have difficulty maintaining reciprocal social relationships, having two-sided conversations, transitioning between activities, and disengaging from idiosyncratic interests. They also have difficulty inhibiting old behaviors in favor of new, more appropriate ones. At school, they struggle to stay organized. They lose or forget to turn in homework. They have difficulty reading for meaning and writing clearly. They may be unable to organize information well enough to correctly answer math story problems. However, despite the fact that deficits in executive functions would appear to map directly related to these inflexible everyday behaviors, it has been challenging to demonstrate this link empirically using clinical neuropsychology measures (see Geurts et al.

2009). It has been suggested that we need better measures that tap “real-world” inflexible behaviors.

Another focus of current research is on how executive functions develop. Adolescent development of executive functions has become an area of active scrutiny given that profound brain changes occur during normative adolescent development, leading to maturation, and providing a window of opportunity for intervention. During adolescence, reductions in cortical gray matter, and increases in white matter volume, result in the refined calibration of the excitatory-inhibitory balance in the PFC, and the strengthening of networks governing cognitive processing. In typical development, most executive functions mature by age 15, although reaction times and performance on more complex tasks and combinations of tasks improve into the 20s.

Future Directions

Fortunately, the advent of new technologies including functional magnetic resonance imaging is helping to advance what we know about brain functioning beyond what could be learned by lesion models. “Cognitive control” is a term evolving in the field of cognitive neuroscience to describe the cognitive processes that traditionally have been thought of as executive functions (Miller and Cohen 2001). The newer cognitive control-based model of PFC function suggests that (1) the PFC is specialized for the representation and maintenance of context information; (2) that context information is maintained in the PFC as a pattern of neural activity; and (3) that context representations mediate cognitive control through interactions that modulate the flow of information in other brain systems that more directly support task performance. Proper functioning of this system is required for (a) effective allocation of attention, (b) inhibition of irrelevant responses, (c) appropriate shifting of frame of reference, (d) relating information appropriately over time and space, and (e) adjusting behavior in relation to the evolving environment. For example, when Americans visit London and attempt to

cross the street, cognitive control must be engaged to avoid the customary practice of looking to the left for oncoming traffic, in favor of looking to the right. In sum, cognitive control must be engaged when overcoming habitual responses, ignoring irrelevant stimuli, or transforming representations. Cognitive control is not required to perform simple or automatic behaviors, but must be engaged to guide action in novel, difficult, or rapidly changing conditions. This is especially important when there is strong competition between the potential responses (such as choosing between the ingrained habit of looking left versus facing the prospect of being run over!).

Specific brain regions thought to be involved in the application of cognitive control include the dorsolateral prefrontal cortex (DLPFC), medial frontal cortex (including the anterior cingulate cortex), and parietal cortex. In the cognitive control model, the DLPFC is believed to maintain appropriate context for action. The anterior cingulate cortex is thought to function as part of a “control loop.” It detects response conflict and signals the DLPFC to allocate more control-related resources. The parietal cortex is activated when it is necessary to switch attentional focus. It also is thought to act as a repository of learned stimulus-response associations from which the DLPFC “selects” the appropriate response. In another emerging model, a hierarchy of brain regions is thought to implement cognitive control. The representation of the highest conceptual level of a task is thought to rely on the anterior or rostralateral PFC.

In conclusion, it is an exciting time for executive functions research, and more work in this area will help to advance the understanding of ASDs. Directions for future executive functions research include:

1. The development of models and measures that better capture what happens in the brain when we are engaged in goal-directed activities. This will include measures of connectivity between different brain regions and neural circuits.
2. Studies that compare these models and measures across other neurodevelopmental disorders. This type of strategy may help us better

understand the genes involved in autism (and other disorders involving similar problems).

3. Studies of executive functions/cognitive control in animals including rodents and non-human primates. These studies can help us tease apart the pathophysiology of disorders. Animal models also can be used to test promising drug treatments.
4. More ecologically valid measures might help in forging associations between the observed day-to-day behavior and models and measures of goal-directed behavior.
5. Most experimental research has used data analytic models that focus on mean group differences. We need studies that consider the role of individual differences in areas such as temperament and personality, stress responsiveness, and motivation in studies of executive functions.
6. Clinical trials of interventions that help us to remediate executive functions deficits.
7. Studies that examine the development of executive functions/cognitive control through the life span.

Executive Functioning and Martial Arts Training in Children with Autism Spectrum Disorder

Janice N. Phung¹ and Wendy A. Goldberg²

¹Department of Psychology,
California State University San Marcos,
San Marcos, CA, USA

²Department of Psychological Science,
University of California, Irvine,
Irvine, CA, USA

Definition

Executive functions (EFs) are a host of interrelated, cognitive processes that drive goal-directed cognitive, emotional, and behavioral functioning. The umbrella term of EFs includes the three core processes of behavioral inhibition (e.g., impulse control), working memory (e.g., holding information in mind while mentally manipulating it), and cognitive flexibility (e.g., transitioning from thinking about one concept to another). Higher-order EFs include fluency, planning, and problem solving/reasoning. Challenges in EFs are common in children with neurodevelopmental disorders such as Autism Spectrum Disorder (ASD). Compared to their typically-developing (TD) peers, children with ASD demonstrate poorer EFs, particularly poorer planning abilities and cognitive flexibility (Hill 2004; Kenworthy et al. 2008).

Different EFs emerge and improve as children age. For example, the capacity to engage in cognitive switching during multidimensional tasks emerges in middle childhood and continues to improve thereafter (Anderson 2002). EFs also appear to be malleable through effortful practice and interventions. A variety of physical and cognitive activities has been proposed to improve EFs in both typical and neurodiverse samples. One of these activities is the practice of martial arts. Martial arts also is an umbrella term and is defined as systemized traditions of combat that are expressed through movement and used for self-

defense, sport/competition, entertainment/recreation, preservation of cultural traditions, and for physical fitness and mental development. Martial arts styles vary greatly in their historical/contemporary contexts, theoretical/practical application, use of weaponry, degree of physical contact, and potential health and fitness benefits.

Our recent research was directed at testing a particular form of martial arts as an intervention to help improve EFs among middle-childhood-aged children with ASD (Phung and Goldberg 2019). In our study, a traditional approach, focused on character development in addition to physical growth, to Mixed Martial Arts (MMA) was implemented as a potential executive functioning intervention for children with ASD. Children were randomly assigned either to attend a set of 26 MMA sessions over 13 weeks (i.e., the intervention) or to be in a waitlist control (WLC) group. Adult instructors and TD peer buddies were trained in how to interact with children with ASD to help deliver the intervention. The MMA intervention included physical movements (e.g., punches and kicks) that increased in complexity (e.g., number of steps) over the course of the program. At each session, the main activity was practiced back-and-forth with TD peer buddies. At the end of the intervention, the MMA group demonstrated improved objective and parent-reported EFs, whereas the WLC group did not show EF improvements between pre- and post-test assessments. Thus, support was found for the effectiveness of a structured, peer-mediated, mixed-martial arts intervention for middle-childhood-aged children with ASD. Our intervention study was the first to demonstrate the benefits of MMA for EFs in children with ASD (Phung 2017; Phung and Goldberg 2019). The authors called for replication with a larger sample and greater balance of gender between the MMA and WLC groups.

Historical Background

Deficits in executive functions (EFs) are common among individuals with ASD and other neurodevelopmental disorders (Diamond 2013;

Hill 2004; Ozonoff and Jensen 1999). Boys appear especially vulnerable to executive functioning problems compared to girls (Diamond 2002), which may be related to the higher incidence of ASD among males compared to females (Baio et al. 2018).

Executive dysfunctions are common in children with ASD but are not part of the core symptomology of ASD. However, EFs seem to be associated with the presence of restricted and repetitive patterns of behavior (RRBs), which are fundamental to the diagnostic criteria of ASD (American Psychiatric Association 2013). RRBs are broad patterns of behaviors, actions, and thoughts that may include intense preoccupations with interests (e.g., overly specific knowledge about a movie that makes it difficult to talk about nonpreferred topics), rigid and non-functional routines (e.g., completing sequences in a specific order), repetitive motor movements (e.g., hand flapping), and nonfunctional use or close examination of parts of objects (e.g., repeated spinning the wheels of a toy car) (Kim and Lord 2010). Severe RRBs hinder adaptive functioning as they cause perseveration on nonfunctional details and limit the ability to generalize or mentally shift previous knowledge to accommodate new information.

Research concerning the consistency of the connection between RRBs and EFs is mixed and the mechanisms linking these phenomena are unclear. For example, one study found that RRBs were associated with the three core EFs of behavioral inhibition, working memory, and cognitive flexibility (Lopez et al. 2005); another study reported that RRBs were only associated with behavioral inhibition (Boyd et al. 2009); and yet another study observed the link between RRBs and EFs only for some measures of RRBs (South et al. 2007). Despite evidence that suggests that executive functioning deficits are linked in part to the diagnostic criteria of RRBs, RRBs in children with ASD manifest at early ages (Richler et al. 2007; Wolff et al. 2014) and EFs are slow to develop in all children. In fact, EFs are the last of the cognitive abilities to reach full maturity, continuing to develop throughout adolescence and into early adulthood. Given its slow

developmental trajectory, researchers have suggested that EFs are malleable and can be improved with effortful practice. An important developmental period in the growth and plasticity of EFs is middle childhood (Best and Miller 2010).

EF abilities appear to worsen with age in ASD samples: Older children with ASD show greater EF problems than do younger children with ASD when compared to typically-developing (TD) peers (Rosenthal et al. 2013). Age has thus emerged as a salient factor when considering interventions to improve EFs. To date, studies examining EFs in middle childhood have focused on interventions to help boost EFs in TD and ASD groups. For example, one study using martial arts training with TD children found that fourth- and fifth-graders benefited more from the EF intervention in terms of improved inhibitory control and working memory compared to the kindergarten and first-graders, who did not show any improvement after receiving the intervention (Lakes and Hoyt 2004). Similarly, a computer-training study with 4- and 6-year-old TD children found no improvements in inhibitory control and working memory; the authors suggested that the children could have been too young (Thorell et al. 2009) (see Diamond and Lee 2011 for a review of EF intervention studies). Thus, middle childhood seems to be an optimal period for these sorts of interventions.

Because children with ASD face difficulties with executive functioning and given that studies have been conducted using martial arts to improve EFs in children with other vulnerable developmental profiles (e.g., low SES; Lakes et al. 2013), we thought that children with ASD might benefit from martial arts training as well. Until recently, few studies had examined the potential of martial arts to benefit EFs in children with ASD. The initial ventures were conducted by Bahrami and colleagues (Bahrami et al. 2012), which focused on the martial art of Kata, and Chan et al. (2013), which focused on the martial art of Nei Yang Gong. The results of these studies will be discussed in the next section.

Our recent research was the first to select a Mixed Martial Arts (MMA) style of martial arts

to implement as an EF intervention to help improve EFs in children with ASD (Phung and Goldberg 2019). A MMA approach was selected for the following reasons, all of which have the potential to specifically target EFs in children with ASD. First, MMA grew in part from Jeet Kune Do, a Chinese martial art that was developed by consolidating elements and techniques from over 20 different martial arts. The goal of Jeet Kune Do was to have different tools that can be used to adapt to different contexts (Lee 1975). Because children with ASD fall widely on the autism spectrum in terms of diverse strengths and weaknesses, an adapted MMA intervention could accommodate to each individual child's abilities by providing various "tools" for the child to use. Second, an adapted MMA approach could help children learn to use these tools across different contexts, which provide the opportunity for the generalization of the skills, thus practicing the EF of cognitive flexibility. Third, compared to some other martial arts styles that are high in intensity and pace, MMA is a relatively low- to moderate-intensity exercise, which past research has indicated could reduce stereotypic behaviors (a form of RRBs) in children with ASD. Specifically, research suggests that low-intensity exercise may help with improving the EF of behavioral inhibition for stereotypic behaviors (Schmitz et al. 2017). Fourth, the MMA style, when taught in a "traditional" rather than "modern" approach, emphasizes self-control of behaviors and emotions rather than physical conditioning and competition (Trulson 1986), which are both important elements of EFs. Lastly, the MMA style involves repeated practice and was designed to increasingly challenge EFs over the course of time, both of which are important elements of effective EF interventions as recommended by Diamond (2012). Considering these reasons together, we selected a traditional approach to the MMA style as our EF intervention for children with ASD given its ability to accommodate to the diversity of skills among children with ASD, the increased likelihood of skill generalization across contexts, its low- to moderate-intensity (which has been recommended for children with ASD), its use of a traditional approach that emphasizes important

elements of EFs, and the learning of techniques that increase complexity over time, thus further challenging and strengthening EFs.

Current Knowledge

In a review paper that compared different exercise interventions (e.g., yoga/dance, swimming, jogging), martial arts training emerged as one of the most effective activities to improve behavioral outcomes in children with ASD (Bremer et al. 2016). To date, only three known studies (including ours) have used martial arts to address EF challenges in children with ASD. In one study, Bahrami et al. (2012) indirectly examined EFs by asking for caregiver reports of stereotypic behaviors (e.g., RRBs) before and after the implementation of a traditional Kata (Japanese forms) program with children and adolescents with ASD. Compared to a no-exercise control group that showed no improvement, the participants who received the Kata training had reduced stereotypic behaviors at post-test, and the benefits extended to caregiver reports at one-month follow-up as well. Because this study found lessened stereotypic behaviors following a martial arts intervention and given the partially supported links between RRBs and EFs, we thought a martial arts intervention might benefit EFs as well.

Another study directly examined one aspect of EFs, self-control (i.e., behavioral inhibition), before and after one month of training in Nei Yang Gong (NYG), a Chinese martial art (Chan et al. 2013). Compared to a control group of children and adolescents with ASD that received Progressive Muscle Relaxation (PMR) training, the NYG group had higher parent-reported self-control and lower daily behavior problems. Furthermore, the NYG group demonstrated increased EEG brain activity during a lab-based EF task compared to baseline, whereas the PMR control group showed no difference. Although participants only received 8 h of martial arts training over the course of one month, the parent-reported and objective EEG findings demonstrated that martial arts could be effective

in improving the self-control aspect of EFs; we wanted to examine whether a martial arts intervention could yield benefits for the other EFs as well.

As mentioned above, our recent study implemented a Mixed Martial Arts (MMA) intervention with middle-childhood-aged children with ASD (aged 8–11 years; 82.4% boys). At pre- and post-test, parents completed the Behavior Rating Inventory of Executive Functions – 2nd edition (BRIEF-2; Gioia et al. 2000) to report on their child's executive functioning. The BRIEF-2 has three indexes of executive functioning: behavior regulation index, emotion regulation index, and cognitive regulation index. Together, these three indexes yield the Global Executive Composite.

During each of the two laboratory visits, children completed a computerized EF task, the Hearts & Flowers test, which used a touch-screen laptop computer. The Hearts & Flowers test measured the three core EFs: behavioral inhibition, working memory, and cognitive flexibility (Davidson et al. 2006; Diamond et al. 2007). The Hearts & Flowers test consisted of one block of same-side stimuli (congruent block), one block of opposite-side stimuli (incongruent block), and one block of trials with both same- and opposite side stimuli (mixed block) (for description of the blocks, see Wright and Diamond 2014). Executive functioning performance on the Hearts & Flowers test was measured for two dependent variables, accuracy and response time (in milliseconds).

After completing the pre-test assessments, children were then randomly assigned to either begin the martial arts intervention in the MMA group, or to not receive any martial arts training in the WLC group. Children in the MMA group then began a 26-session (2 times per week), 13-week MMA intervention, which took place at a local martial arts studio. The lead author collaborated with the studio's instructors to develop the content of the curriculum, which increased in complexity over the course of the 26-session program. For example, in the first third of the program (Weeks #1 through 4) the instructors taught movements (striking, i.e., punches and kicks) that were made

up of 2- to 3-step sequences. In the second third of the program (Weeks #5 through 8), the instructors taught movements (grappling) that were now 4- to 9-step sequences. In the final third of the program (Weeks #9 through 13), instructors taught movements (striking and grappling) that consisted of 4- to 13-step sequences. Over the course of the 26-session program, the movements not only grew in complexity, but children were also taught to generalize previously learned skills to build upon the new material. Unique to the program was the inclusion of peer buddies, typically-developing (TD) children who were students in other classes at the studio. Peer buddies volunteered to assist in the program and acted as training partners with the children with ASD.

In terms of the structure of each class, each session began with the children lining up and bowing-in to pay respects to the instructor. Next, the instructor led children in a brief meditation and breathing activity, focusing on the goals of the day. Warm-up activities that included activities like jogging, footwork, stretching, and jumping were followed by the main activity of the specific class session. During the main activity, the instructor taught the martial arts movements (e.g., striking, grappling) and children with ASD were paired with TD peer buddies to then practice the taught movements. As mentioned previously, the curriculum for the main activity increased in complexity over the course of the 26-session program. Each class ended with a social game and paying respects to the instructor and classmates. At the end of the intervention, children in both the MMA and WLC groups returned to the lab testing space for post-test assessments using the parent-reported BRIEF-2 (Gioia et al. 2000) and child performance on the computer-based Hearts & Flowers test (Davidson et al. 2006).

In general, results from the study found that both parent-reported and computer-based assessments of EFs improved with the MMA group, but not with the WLC group. Specifically, for parent-reported child EF on the BRIEF-2 questionnaire, children in the MMA group had improved EFs on the behavior regulation and emotion regulation indexes but not on the

cognitive regulation index, compared to the reports from parents of children in the WLC group. Parents of children in the MMA group also reported improved overall EF on the Global Executive Composite. In terms of computer-based assessment of EF, the MMA group demonstrated improvements on the accuracy variable on the congruent and mixed blocks but not on the incongruent block. The WLC group did not improve in their accuracy on any of the blocks. Neither the MMA nor WLC groups demonstrated performance differences on the response time variable.

The results of this study demonstrated that a traditional approach to MMA helped improve both parent-reported and objectively-measured EF in middle-childhood-aged children with ASD. Limitations of our study include gender distributions in the two groups and variability in attendance. We still seek to understand why some EF domains showed improvement but not others.

The few studies on executive functioning and martial arts in children with ASD share some similar characteristics for study design and design of the intervention. In terms of study design, all three studies (Bahrami et al. 2012; Chan et al. 2013; Phung and Goldberg 2019) randomly assigned participants to either the martial arts or control group. Whereas Bahrami et al. (2012) and Phung and Goldberg (2019) included a no-martial arts control group in which participants were passively awaiting the post-test session, Chan et al. (2013) had their control group actively participate in the muscle relaxation training program at the same time that the martial arts group received their intervention program. All three studies included parent-reported assessments of child executive functioning; only Bahrami et al. (2012) included multiple informants (e.g., parents, caregivers, and teachers). Chan et al. (2013) and Phung and Goldberg (2019) both included objective measures of child executive functioning to supplement the parent report. In terms of number of test sessions, all three studies conducted pre- and post-test assessments, but only Bahrami et al. (2012) conducted an additional one-month follow-up after the intervention concluded. Finally, of the three studies, Phung and Goldberg (2019) had the most discrete age range (ages 8- to 11-years).

The other two studies included participants whose ages ranged from childhood (ages 5–6 years) through adolescence (ages 16–17 years).

Intervention design for the three studies also varied widely. First, the three studies executed different styles of martial arts: Bahrami et al. (2012) implemented Kata, Chan et al. (2013) implemented Nei Yang Gong, and Phung and Goldberg (2019) implemented Mixed Martial Arts. Although the three martial arts styles varied, they were all taught using a traditional approach, which emphasized character development in addition to physical conditioning rather than a modern approach that typically focuses on sport and competition (Trulson 1986). The intervention designs also varied in their duration (i.e., how long the program lasted from start to finish). The Bahrami et al. (2012) intervention was the most time intensive and took place four times per week for 14 weeks (56 sessions), followed by Phung and Goldberg (2019), which took place two times per week for 13 weeks (26 sessions), and lastly, Chan et al. (2013), which took place two times per week for four weeks (8 sessions). A similar pattern followed for intervention dosage or intensity (i.e., how much of the intervention to be delivered to participants). Again, martial arts participants in the Bahrami et al. (2012) study received the highest total dosage of martial arts intervention at approximately 3120 min. Martial arts participants in the Phung and Goldberg (2019) study received the second highest total dosage of martial arts intervention at approximately 1170 min. Lastly, martial arts participants in the Chan et al. (2013) study received the smallest total dosage of martial arts intervention at approximately 480 min. (Note that these were the expected dosages as reported by the researchers.)

Future Directions

Children with ASD often face difficulties with tasks that require the use of executive functions (EFs). Fortunately, EFs are malleable, especially during middle childhood compared to earlier developmental stages. There are a number of

activities that have been studied to improve EFs. Considering the recent martial arts intervention studies reviewed here, training in martial arts appears to improve EFs in children with ASD, compared to those in control groups that do not participate in martial arts. However, the field is comparatively new, and more research is needed.

Following up on our recent study (Phung and Goldberg 2019), future work should explore why some EFs improved but not others with the Mixed Martial Arts (MMA) intervention. Replication is also needed with a larger sample and a greater balance of genders between the MMA and WLC groups. Completion of the expected number of sessions was challenged in part by the many different types of obligations juggled by parents raising children with ASD (Myers et al. 2009). Future MMA intervention studies could offer more MMA classes throughout the week and weekend to accommodate to families' busy schedules.

Martial arts training includes mindfulness, physical activity, and cognitive complexity, but research to date has not yet isolated these three components. Future studies should include a mindfulness or yoga comparison group to determine if improvements are possibly due to the meditative component of the martial arts since mindfulness training has been linked to improved EFs in TD children (Flook et al. 2010). Although Chan et al. (2013) had a comparison group of children with ASD who participated in a meditation-type of activity, the martial arts group showed better overall self-control than the control group after the respective interventions. Additional research is needed to expand EFs in addition to self-control (e.g., working memory and cognitive flexibility).

Furthermore, to address the question of which physical activity matters most, future research should include a comparison group of children with ASD enrolled in non-martial arts sports teams (e.g., basketball, soccer, baseball, etc.) or individual aerobic exercise (e.g., jogging, swimming, etc.). As evidenced by prior studies, physical exercise has been linked to a decrease in stereotypy in children with ASD (e.g., Schmitz et al. 2017). Therefore, the inclusion of a sport

or aerobic exercise comparison group may be useful in determining if the physical activity drives the improvements in EFs, or if there is something unique about training martial arts in addition to its physical benefits.

In future research, the variability of dosage should be taken into consideration and streamlined across studies to allow for comparability. In a systematic review of behavioral outcomes following exercise interventions for children with ASD, Bremer et al. (2016) commented that a "more is better" approach is often taken with behavioral interventions, but this may not hold true regarding exercise and outcomes. For example, a ceiling effect could occur where observed benefits appear to plateau (Bremer et al. 2016). Alternatively, excessive or too much of an exercise intervention could result in the regression of progress. For example, Schmitz et al. (2017) found in their study that the most exhaustive exercise condition led to increased stereotypic behaviors in children with ASD compared to the less exhaustive exercise conditions. Fidelity checks are recommended to confirm that the intervention is in fact implemented as it was initially intended (Dumas et al. 2001).

Finally, future work should also consider the cognitive complexity component that is part of martial arts training. Because martial arts training includes mindfulness, physical activity, and cognitive complexity, future research should isolate these three components to determine if they each uniquely contribute to improving EFs, or whether the observed improvements are due to their interaction when implemented as part of martial arts training.

Martial arts training not only contributes to improving executive functioning, but could also contribute to improving other domains that are challenged in children with ASD, such as social dysfunction and behavior problems (e.g., Movahedi et al. 2013). Martial arts training is a feasible and ecologically valid means to improve EFs in children with ASD, and might also improve other areas of development. Benefits conferred from improvements in executive functioning likely extend beyond the cognitive and behavioral domains to include better mental,

physical, and social health, and overall improved quality of life in children with ASD. Indeed, the current state of knowledge is promising, and the future of this work is wide and has the potential for expansion.

Executive Functions, Social Impairment, Friendship Quality, and Adjustment in HFA with ASD

Rebecca Lieb

NeuroDevelopmental Science Center, Akron Children’s Hospital, Akron, OH, USA

Definition

Social impairment is a hallmark feature of autism spectrum disorder (ASD). Research has shown the impacts of social deficits, particularly with high functioning ASD, including challenges with friendship development, loneliness, and depressive symptoms. Factors are also being identified that influence social skills, including executive functions (EF). It is important for the research and clinical community to understand the direct and indirect influence that these constructs have on each other as this has treatment implications. To support a child with ASD as they are experiencing social isolation or depression, it may be necessary to recognize and help build other skill areas such as cognitive flexibility, emotion regulation, inhibition, etc., which may assist in improving their socio-emotional outcomes.

Current Knowledge

Research has consistently shown comorbid depressive symptoms in youth with autism spectrum disorder (ASD; e.g., Ghaziuddin et al. 2002; Volkmar and Klin 2005; Klin et al. 2005; Lopata et al. 2010). Although studies vary widely in their reports of prevalence rates (see DeFilippis 2018 for a review), many comorbidity rates are as high as 53–54%, compared to the recent National

Institute of Mental Health statistic of 9.4% in the general adolescent population (Kim et al. 2000; Mayes et al. 2011; Ghaziuddin et al. 1998; Solomon et al. 2012; Thapar et al. 2012; National Institute of Mental Health 2019). Higher functioning youth with ASD are often aware of their differences in relation to same-aged peers (Volkmar and Klin 2005) and can be frustrated with social difficulties (Klin et al. 2005), which can lead to higher rates of anxiety and depressive symptoms than typically developing youth (e.g., Kim et al. 2000). This population exhibits greater levels of loneliness compared to neurotypical peers (e.g., Bauminger and Kasari 2000; Ghaziuddin et al. 2002; Lasgaard et al. 2009) and reports more social loneliness (e.g., Bauminger et al. 2003), suggesting they are not only aware of the concept of loneliness, but recognize it in themselves. Even in early elementary school, children with ASD are already reporting feeling symptoms of loneliness and being out of place at school (Zeedyk et al. 2016).

A direct association has been established between social impairment and adjustment (e.g., Barnhill 2001; Vickerstaff et al. 2007; White and Roberson-Nay 2009). The quality of social interactions in youth with ASD are often different, including fewer social initiations, shorter social interactions, isolated or more parallel play, and challenging or repetitive behaviors that may interfere with successful social interactions (see McConnell 2002 for a literature review). In addition, children in general often gravitate toward others with common interests; therefore, if a child with ASD has a focused interest on an uncommon topic (e.g., Titanic, fire extinguishers, box fans, the War of 1812), this can impact social experiences and friendships. Not surprisingly, youth with ASD report having fewer friends and spending less time interacting with friends. A review of 235 adults and adolescents with ASD found that only 8.1% reported interacting with same-aged friends on a weekly basis outside of an organized activity and 46.6% of the sample reported having no same-aged friends (Orsmond et al. 2004). Zeedyk et al. (2016) found almost 40% of an early elementary school ASD sample reported challenges with developing friendships

at school. This is despite youth with ASD having similar expectations for friendships compared to typically developing peers (Bottema-Beutel et al. 2019). Furthermore, Pouw et al. (2013) found that poorer friendship quality was associated with increased self-reported depressive symptoms in boys with ASD. While some reviews of the literature find that increased reports of loneliness are primarily from samples of adolescents with ASD, other studies find similar reports of loneliness in pre-adolescents (see Deckers et al. 2017 for an example). Further, Deckers et al. (2017) found significantly higher levels of loneliness compared not only to a non-clinical control group but a clinical-ADHD group.

Executive function (EF) impairments likely affect one's ability to successfully interact socially with others (e.g., Joseph 1999; Solomon et al. 2004). EFs are a set of cognitive behaviors that allow for higher level planning and organization (Wong et al. 2006). Research shows that youth with ASD demonstrate EF impairment compared to neuro-typical peers (e.g., Russo et al. 2007; Verte et al. 2006; Akshoomoff 2005; Semrud-Clikeman et al. 2014) and even those with ADHD (e.g., Semrud-Clikeman et al. 2010; Hughes 2011) although with the allowance of the dual diagnosis of ASD and ADHD in the DSM-5, recent research has suggested a more nuanced EF differentiation between the two diagnoses (e.g., Berenguer et al. 2018). Domains impacted include set shifting and cognitive flexibility (Ozonoff and Jensen 1999; Joseph 1999; Russo et al. 2007; Verte et al. 2006; Semrud-Clikeman et al. 2010), working memory (e.g., Russo et al. 2007; Rogers and Bennetto 2000; Verte et al. 2006), emotional control (Konstantareas and Stewart 2006; Semrud-Clikeman et al. 2010), and planning (e.g., Semrud-Clikeman et al. 2010). Results suggesting deficits in inhibition are less conclusive (Rogers and Bennetto 2000; Semrud-Clikeman et al. 2010; Verte et al. 2006; Narzisi et al. 2013). Inconsistencies in results may relate to differences in how studies address moderators and what measures of EF are used (see Demetriou et al. 2018 for further discussion).

There is further evidence demonstrating the impact of EF deficits on many areas of ASD

including social impairment, friendship quality, and even adjustment. Carrington et al. (2003) documented cognitive inflexibility when making decisions about friendships in five youth with ASD. Leung et al. (2016) found that parent-reported metacognitive EF deficits (working memory, organization, initiation, etc.) predicted increased greater social impairment in youth with ASD but not typically developing controls. They linked this to challenges with theory of mind, which requires one to think “metacognitively.” Interestingly, their study found that both ASD and control groups had increased social impairment as parent-reports of behavior dysregulation increased. Furthermore, the impact of social impairment on adjustment in youth with ASD may be impacted by poorer EF, making processing and utilizing social information even more challenging. Lieb and Bohnert (2017) assessed parent report of EF and social impairment and parent and self-reported friendship quality, loneliness, and depressive symptoms in a sample of high functioning ASD youth. Not only did they find direct relations between poorer EF and more adjustment difficulties, but structural equation modelling found good fitting models, whereby social impairment mediated domains of EF (inhibition, shifting, emotional control, working memory). Thus, greater EF impairment was linked to greater social impairment and subsequently poorer adjustment. Interestingly, there was less evidence to support the mediating relation of friendship quality with the exception of its impact on the relation between emotional control and loneliness.

Future Directions

Longitudinal studies examining the direct and indirect effects of EF, social impairment, and friendship quality are necessary. While it is possible that having stronger EF skills leads to better friendship quality or social skills, it is unknown whether those with better abilities to make and keep friends may more easily be able to improve upon and develop their EF skills over time. Furthermore, understanding whether the relations between these domains

differs in females compared to males is important, as emerging research has continued to demonstrate the subtle yet important differences in the behavioral presentation of ASD in females and specific gender differences in social experiences including friendship quality and social motivation for youth both with and without ASD (e.g., Sedgewick et al. 2016). Additionally, developing assessment measures with excellent norms for populations across the autism spectrum will allow for more accurate parent- and self-report. Relatedly, it is important to evaluate and possibly refine our operational definitions of these constructs. For example, Donaldson et al. (2018) propose that nuanced differences in the friendship literature may be impacted by how neuro-typical youth and those with ASD define friendships and social relationships, which can impact how we approach both research and intervention. Finally, it is important to further explore other influential factors, including cognitive and language abilities, and co-morbid medical and/or mental health diagnoses to understand the differential impact that belonging to “multiple groups” may have on a person’s outcomes. For example, Berenguer et al. (2018) found that children with comorbid ASD and ADHD had great EF deficits than those with ASD only and that the ASD and ADHD group had more behavioral challenges than either the ASD only or ADHD only groups. Better understanding the complexities of the whole person can help clinicians, teachers, and even families and caregivers address challenges more effectively.

²Department of Health and Human Performance, Texas State University, San Marcos, TX, USA

Definition

Physical activity (exercise) can be defined as the expenditure of energy through body movements produced by skeletal muscles (World Health Organization [WHO] 2017). Physical activity

may be structured (organized sporting events) or unstructured (use of playground equipment) and may involve commonly recognized physical exercises (e.g., running and lifting weights) as well as activities such as doing household chores and gardening (Ayvazoglu 2009; Biddle 1994; Obrusnikova and Miccinello 2012). The National Heart, Lung, and Blood Institute (NHLBI 2016) defines four types of physical activity: (a) aerobic exercises involving the sustained movement of larger muscles, as in jogging and cycling; (b) muscle-strengthening exercises such as lifting weights, push-ups, and sit-ups designed to increase muscle strength and endurance; (c) bone-strengthening exercises that require supporting one's own body weight (e.g., rope climbing and gymnastics); and (d) stretching, which improves flexibility by extending muscle groups through a range of body motions. Physical activity may be further classified according to intensity and physical exertion (i.e., heart and breathing rate) as either low, moderate, or vigorous. For example, in most cases light walking slightly increases heart rate and respiration and could be considered low intensity. Jogging might be counted as a moderate-intensity exercise because it results in a higher heart rate, but individuals can still perform for a relatively long period of time without fatigue, while sprinting would be classified as vigorous intensity, if it substantially increases heart rate and breathing.

Individuals with autism spectrum disorder (ASD) experience a number of deficits and challenges in areas related to physical activity and exercise (Fournier et al. 2010; Hocking and Caeyenberghs 2017). For example, people with ASD are reported to display difficulties on measures of balance, postural stability, muscle strength, and gait when compared to individuals without ASD (Bhat et al. 2011; Liu and Breslin 2013; Provost et al. 2007; Staples and Reid 2010). Furthermore, people with ASD are less likely to engage in moderate to vigorous physical activity and participate in organized sports. They tend to live sedentary lifestyles as compared to others without ASD (Bandini et al. 2013; Obrusnikova and Cavalier 2011; Pan 2009; Pan and Frey 2006; Pan et al. 2017; Pan et al. 2011;

Rimmer et al. 2004; Rimmer and Rowland 2008; Rimmer et al. 2007; Todd and Reid 2006). Regular exercise participation results in a number of physical and psychological benefits (e.g., reduces risks of cardiovascular disease, certain cancers, diabetes, and obesity) and may facilitate a reduction in stress as well as provide opportunities for community involvement, recreation, and socialization (Ensel and Lin 2004; Hillier et al. 2011; USDHHS 2002). Given these health and wellness benefits, research has examined the use of exercise in the education and treatment of people with ASD (Bremer et al. 2016; Lang et al. 2010; Tan et al. 2016).

Historical Background

In general, the health and wellness benefits of physical activity and exercise have been widely recognized for centuries and the positive effects have been well documented (Janssen and Leblanc 2010; National Association for Sport and Physical Education [NASPE] 2002). However, research on the potential benefits of exercise for people with ASD began to appear more regularly in the 1980s (Lang et al. 2010). In addition to improved physical fitness, several early studies investigating the effect of exercise in people with ASD reported benefits specifically related to ASD characteristics. For example, Watters and Watters (1980) reported a 32.7% mean decrease in the self-stimulation in children with ASD following physical exercise. Allen (1980) found that jogging reduced the frequency of problem behaviors among children with ASD; similarly, Kern et al. (1982) reported that jogging decreased self-stimulation and increased appropriate play and academic responding. These findings have been replicated by different research teams using a variety of research designs (Bachman and Fuqua 1983; Gordon et al. 1986; Kern et al. 1984; Levinson and Reid 1993; Reid et al. 1988). Overall, early research studies suggest that exercise can reduce stereotypic behaviors and improve adaptive responses in children with ASD.

Since the 1980s, research has progressed to studying the relative benefits of low, moderate, and vigorous exercise involving diverse types of physical activities on various dependent variables and target behaviors. Additionally, research has continued to examine the physical activity and exercise benefits and has started to investigate various potential biological and behavioral mechanisms that may account for improvements in nonphysical domains (e.g., how/why does exercise reduce stereotypy). Although clear mechanisms of action have not yet emerged from the literature and studies investigating various intensity levels have been inconsistent, the current corpus of research literature includes a sufficient number of rigorous studies to identify a few well-established findings involving ASD and physical activity.

Current Knowledge

During early childhood, physical activity levels of young children with and without ASD are similar (Bandini et al. 2013; Pan 2009). However, in the absence of intervention, school-aged children with ASD are likely to spend less time engaging in moderate physical activity and participating in fewer after-school physical activities than their typically developing peers (Bandini et al. 2013; Liu and Breslin 2013; Liu et al. 2016; Provost et al. 2007). Differences in physical activity levels may be due to lack of social interaction and motor skill competence, obesity, and reduced opportunity to participate (MacDonald et al. 2011; McCoy et al. 2016).

Increased physical activity and exercise has been shown to result in improved cardiorespiratory endurance, flexibility, balance, muscle strength, and fitness similar to children without ASD. For example, Fragala-Pinkham et al. (2008) reported improved cardiorespiratory endurance and muscle strength in children with ASD following an aquatic physical activity participation. Although a few studies have reported differences in physiological responses to exercise between groups of children with and without ASD (e.g., lower heart rate in ASD group relative to control;

Pace and Bricout 2015), there appears to be some consensus that exercise improves the health of people with ASD similar to that of people without ASD.

Increased physical activity and exercise-based interventions have also been linked to improvements in the cognitive, social, and behavioral characteristics often associated with ASD (Tan et al. 2016). A reduction in stereotypy for a brief period of time following exercise is among the most commonly reported beneficial outcomes in the current literature (Bremer et al. 2016; Lang et al. 2010; Neely et al. 2015; Petrus et al. 2008). Unfortunately, the reduction in stereotypy appears to be temporary and stereotypy tends to return to baseline levels within 2 h post exercise (Liu et al. 2016).

The evidence-base supporting improved cognitive and social performance in people with ASD following exercise is not as well established but should still be considered promising. Tan et al. (2016) conducted a systematic review of 22 studies involving a combined total of 579 participants with ASD between the ages of three and 25 years old and reported a small-to-medium effect of exercise on cognitive performance. In addition, Anderson-Hanley et al. (2011) found significant improvements in the measures of sustained attention and working memory following physical exercise. Similarly, improved academic performance (e.g., accuracy and efficiency in completing school tasks) and school-readiness behavior (compliance and on-task behavior) have been reported in multiple studies (ElGarhy and Liu 2016; Neely et al. 2015; Rosenthal-Malek and Mitchell 1997).

For clinicians and those involved in designing programs for people with ASD, the bottom line is that increasing physical activity in children with ASD appears to be an increasingly common treatment goal, and the current research base clearly indicates that opportunities for exercise, sports, and other physical activity should be embedded within school and residential programs serving people with ASD (Bremer et al. 2016; ElGarhy and Liu 2016; Liu and Breslin 2013; McCoy et al. 2016; Sowa and Meulenbroek 2012; Tan et al. 2016).

Future Directions

Recent systematic reviews and meta-analyses of the peer-reviewed research literature related to physical activity and exercise for people with ASD have identified several directions for future research, including (a) evaluating long-term outcomes of physical activity; (b) elucidating the physiological or psychological mechanisms that cause, contribute, or impede beneficial outcomes; and (c) determining efficient and effective approaches to embedding exercise into routines and existing treatment protocols (Bremer et al. 2016; Lang et al. 2010; Lewis et al. 2017; Tan et al. 2016). This future research should focus on evidence-based components and consider incorporating technology. For example, video games that require physical activity and software applications (apps) that prompt and reinforce physical activity may facilitate inclusion of exercise into daily routines while also providing motivation by making physical activity easier and more enjoyable (Hamilton et al. 2010).

Some of the more promising outcomes of increased physical activity for people with ASD require additional replication and extension. For example, improved cognitive and social functioning have been reported in a number of studies, but the wide range of cognitive and social dependent variables measured in those studies as well as the variety of exercise and physical activities that have been investigated limit the certainty and clarity of this corpus of research. Cognitive performance has been considered in terms of retention (memory), academic performance, among other measures of executive functioning following aerobic, muscle-strengthening, bone-strengthening, and stretching exercises with inconsistent results both within and across studies (Tan et al. 2016). Similar issues apply to the purported social functioning effects of exercise, and it has been suggested that improved approaches to measuring social performance are necessary. Additionally, the relative effects of low, moderate, and vigorous activity are not yet clear. For example, Olin et al. (2017) reported that high-intensity (vigorous) exercise exacerbated stereotypy, while low- to moderate-intensity exercise

occasioned large significant reductions; however, other studies have conversely reported vigorous-intensity exercise to have a more pronounced effect than low- and moderate-intensity (Kern et al. 1984). Currently, it is not clear if such discrepancies across studies are due to uncontrolled differences in participants, types of exercise, criterion used to classify intensity, or other similar variables. Finally, it may be fruitful to consider whether physical activity conducted immediately prior to other forms of therapy (e.g., language training) enhances the desirable outcomes of existing evidence-based interventions for children with ASD (Pan et al. 2017; Tan et al. 2013).

Experimental Research

► Qualitative Versus Quantitative Approaches

Explicit Memory

Diane M. Lickenbrock

Human Development and Family Studies, The Pennsylvania State University, University Park, PA, USA

Synonyms

Declarative memory; Fact memory

Definition

A specific type of memory that involves intentional, conscious recollection. Explicit memory

is often assessed by using tasks that require recognition and recall. Research has shown that individuals with Autism Spectrum Disorder (ASD) have intact explicit memory, although they use a different memory retrieval process. Individuals with ASD and intellectual disability show greater impairments in explicit memory compared to high-functioning individuals with ASD.

Expressive Dysphasia

M. S. Hope Morris
Communication Sciences and Disorders, The
University of Vermont, Burlington, VT, USA

Synonyms

[Developmental language disorder](#); [Expressive language disorder](#); [Specific language impairment](#)

Definition

In neurological contexts, language impairment is identified as either acquired (aphasia) or developmental (dysphasia). An expressive dysphasia is a language disorder linked to deviation or an early injury to areas of the brain that are specialized for language functions. In expressive dysphasia, children have difficulty with verbal expression but have adequate language comprehension skills. Difficulties can be noted in putting words into coherent sentences, using appropriate grammar, and recalling words. Expressive dysphasia is often observed in children with autism spectrum disorders (ASD) and can be noted across the spectrum regardless of severity. Issues noted specifically in children with ASD include difficulties with word order in sentences (syntax), difficulties using appropriate word morphology (word endings) and grammar (especially pronouns), as well as noted difficulties in semantic organization and word finding.

Expressive Language

M. S. Hope Morris
Communication Sciences and Disorders, The
University of Vermont, Burlington, VT, USA

Synonyms

[Expressive communication](#); [Oral language](#); [Spoken language](#)

Definition

Expressive language is a cognitive process that is involved in the transmission of oral, symbolic, or written language and allows for communicating

one's ideas, desires, or intentions to others. Expressive language is composed of form (grammar and syntax), content (semantics or meaning), and use (communicative function and intent). Expressive language can take many forms including verbalizations, sign language, gestures, pictures, written words, and, in some cases, voice output communication devices. Individuals with autism spectrum disorders (ASD) can have difficulty with expressive language in any of the aforementioned areas, especially in the area of language use.

Expressive Language Delay

- [Expressive Language Disorder](#)

Expressive Language Disorder

M. S. Hope Morris

Communication Sciences and Disorders, The
University of Vermont, Burlington, VT, USA

Synonyms

[Developmental language delay/disorder](#); [Expressive language delay](#); [Specific language impairment](#)

Definition

Expressive language disorder indicates an individual is likely to understand more than what he/she is able to communicate. This means a person's receptive language (comprehension) is better than his/her expressive language (use of language). This disorder is often associated with a developmental language delay. Expressive language disorders can also be acquired (as a result of brain injury/damage), as in aphasia. A developmental delay in expressive language is more common in children and can occur in a child with normal intelligence or co-occur with cognitive impairment or other developmental disorders a child might experience. Expressive language disorder can be observed in both verbal and written communication forms. Children with autism spectrum disorders (ASD) often present with expressive language disorders. Many children with ASD begin speaking later than typically developing children and often demonstrate a significantly slower development of expressive language through the preschool years. In particular, children with ASD present with differences in the social use of language (pragmatics).

Expressive Vocabulary Test II

Maura Moyle and Steven Long

Speech Pathology and Audiology, Marquette
University, Milwaukee, WI, USA

Synonyms

[EVT-2](#)

Description

The *Expressive Vocabulary Test, Second Edition* (EVT-2) is a quick, norm-referenced assessment designed to measure expressive vocabulary and word retrieval for Standard American English. Norms are provided for a wide age range (i.e., 2 years and 6 months to beyond 90 years of age). Items require examinees to provide either

labels or synonyms. For each item, examinees are shown a colored picture and prompted by the examiner to provide a one-word response (e.g., “What is this animal?” or “Tell me another word for jacket.”). The EVT-2 is co-normed with the *Peabody Picture Vocabulary Test, Fourth Edition* (PPVT-4; Dunn and Dunn 2007), a measure of receptive vocabulary (i.e., understanding of spoken words). When both the PPVT-4 and EVT-2 are administered, direct comparisons can be made between a client’s receptive and expressive vocabulary. The EVT-2 has two parallel test forms (A and B) so it may be used for progress monitoring. EVT-2 materials include an examiner’s manual, test easel (either form A or B), and 25 record forms (additional forms can be purchased separately). Users can choose to purchase ASSIST, a software program for electronic scoring, which provides various types of group and individual reports. Examiners administering the EVT-2 must be trained and experienced in test administration and scoring. Only qualified educational and psychological professionals should interpret the test results.

The EVT-2 manual provides clear guidelines for administration and scoring. Each form (A or B) contains 190 test items presented in order of increasing difficulty. In addition, two practice items are presented to ensure the client understands the procedure. The EVT-2 is administered individually, and testing time is estimated to be 10–20 min, depending on age and ability (e.g., individuals with larger vocabularies tend to require more testing time). Start points are based on the client’s chronological age. The basal rule is five consecutive correct responses, and the ceiling rule is five consecutive incorrect responses. A stimulus prompt and all possible correct answers are provided for each item on the score form. The most common incorrect answers are also listed. Some incorrect answers are tagged with a “P” indicating that the examiner should provide an additional prompt to encourage a correct response from the examinee. The manual does not provide an explanation as to why some incorrect answers are prompted, while others are not. Although the test is officially untimed, the manual suggests a 10^{-s} limit for responding to

each item, especially if the EVT-2 is to be used as a measure of word retrieval. Items are scored as incorrect (“0”) or correct (“1”) on the score form during test administration. Space is provided for examiners to write responses that are not listed on the score form for later scoring.

The EVT-2 provides numerous options for converting the data and guidelines for interpreting the results. First, raw scores are calculated by taking the highest item in the client’s ceiling and subtracting errors for all items administered. Items below the basal are considered to be correct. Raw scores are converted to standard scores (mean = 100, standard deviation = 15) based on either age or grade (fall or spring). A raw score can also be converted to a growth scale value (GSV) which is helpful for tracking a client’s vocabulary development over time. The GSV is an indicator of absolute level of performance rather than a norm-referenced score. If a client’s score increases on the EVT-2 upon subsequent administrations, then his or her GSV will also increase (versus norm-referenced scores which may decrease over time if a client’s growth is below average compared to his or her peers). Tables are also provided for converting standard scores to percentile ranks, normal curve equivalents, and stanine scores. If the PPVT-4 was also administered, tables are provided to determine whether the absolute difference between the EVT-2 and PPVT-4 scores is statistically significant.

The EVT-2 also provides tools for conducting various qualitative interpretations of a client’s performance. These analyses include expressive versus receptive vocabulary, home versus school vocabulary, vocabulary by part of speech (i.e., noun, verb, attribute), vocabulary by tier using a three-tier model (i.e., tier 1 – vocabulary common in conversation, tier 2 – vocabulary common in school curricula, tier 3 – technical vocabulary; Beck et al. 2002), and crossover vocabulary sampling between the EVT-2 and PPVT-4 (i.e., comparing items common to both assessments). Worksheets are provided in the test manual to complete these qualitative analyses by hand, or the ASSIST software will compute them upon entering a client’s performance item by item.

Historical Background

The previous edition of this assessment was the *Expressive Vocabulary Test* (EVT; Williams 1997). The first step in the 5-year revision process was to survey and interview current users of the EVT to gather ideas for improvements. In addition, a panel of ten consultants representing the perspectives of several ethnic minorities was formed to examine the test for cultural and linguistic biases. Offensive items and items that were potentially biased were eliminated. Several updates were subsequently made to the EVT: two parallel test forms were developed, more words representing everyday vocabulary were included, more words found in oral directions given in the classroom were included, labeling-type items were included throughout the range of difficulty (versus just synonym types at the higher age ranges), a specific stimulus question was included for each item on the score form, several items were dropped, all of the stimulus pictures were updated, and the EVT-2 was co-normed with the PPVT-4.

In order to create a parallel test form, many new words needed to be added. Two guidelines were followed for choosing which words were included in the initial tryout pool. The first was to choose words that represented Standard American English vocabulary encountered in typical life experiences. The second guideline was to choose words that occurred with relatively high frequency (in order to measure word retrieval). Several published lists of word frequencies were consulted for the selection of new words (see the test manual for the specific references). A set of 400 items were eventually chosen for the two national tryout studies. Guidelines for scoring were based on the results of the first tryout study of 1,451 participants and also based on several reference materials (e.g., dictionaries and thesauruses). Specific details on choosing correct and incorrect responses were not provided in the manual. Items were subsequently analyzed in terms of item difficulty, item discrimination (i.e., ability to differentiate examinees with lower and higher vocabulary levels), and item bias (i.e., examining if an item was more difficult for one group of examinees than another). The items were reviewed

by a second panel of 15 individuals representing various ethnic backgrounds to examine cultural sensitivity and fairness with inappropriate items subsequently eliminated. Next, a second national tryout with 852 participants was conducted, and similar item analyses were completed. Based on the two tryout studies, the EVT-2 standardization versions were created and norms were developed.

Psychometric Data

The sample used to standardize the EVT-2 and create the test norms consisted of 3,540 individuals at 320 sites nationwide ranging in age from 2 years and 6 months to over 90 years of age. The demographic characteristics of the participants (i.e., gender, ethnicity, socioeconomic status, geographic region, special education status) closely resembled the larger population of the United States according to the 2004 US Census. The sample was divided into 28 age groups, with 60 to 200 individuals within each group (all but the two oldest groups contained at least 100 individuals). Grade norms are based on a subset of 2003 cases with 100 to 233 students per grade. Approximately half of the participants were administered form A of the EVT-2 and half completed form B. A subset of 507 participants were administered both forms. Mean scores across age groups indicate no floor or ceiling effects for either form. In addition, the test manual provides evidence suggesting that the two forms are of similar difficulty.

Reliability of the EVT-2 was assessed through analyses measuring internal consistency (i.e., split-half and alpha reliabilities), alternate-form reliability, and test-retest reliability. Measures of internal consistency were calculated for the 28 age groups and for both EVT-2 forms (A and B). Split-half reliability coefficients were high, ranging from 0.88 to 0.97, and alpha coefficients were also high, ranging from 0.93 to 0.98, indicating a high degree of internal consistency. Alternate-form reliability resulted in correlations ranging from 0.83 to 0.91 for the subset of participants who were given both forms A and B, indicating that the two forms provide similar results. Another

subgroup of 348 examinees across five age groups was given the EVT-2 twice with an interval of 2 to 6 weeks between administrations. The resulting test-retest reliability was high, with coefficients ranging from 0.94 to 0.97, suggesting excellent stability of scores. Inter-rater reliability was not reported.

The validity of the EVT-2 was assessed in terms of content validity, its relationship to age, and correlations to other tests (i.e., criterion-related validity). In addition, its sensitivity to measuring differences in various special populations was examined. The author refers to the process of item selection (discussed above) as evidence for content validity. As stated earlier, items were chosen if they were of moderate to high frequency according to various published resources and if they represented everyday experiences. In addition, items were reviewed by content specialists and panels examining cultural and linguistic biases. No more detail on the processes of item generation or selection is provided. Also, the manual does not report mean scores by race or ethnicity which would provide additional evidence for the cultural and linguistic fairness of the test. EVT-2 mean test scores increase rapidly in childhood, while growth is gradual in adolescence and young adulthood. Scores plateau through middle adulthood and then decline gradually at older ages. This pattern of results is what would be expected given what is known about cognitive and linguistic development. Therefore, the EVT-2 appears to be sensitive to age-related changes in expressive vocabulary skill. In terms of criterion-related validity, the relationships between the EVT-2 and other measures of language and reading were examined using subsets of the norming sample (consisting mostly of children and adolescents), including the PPVT-4, the *Comprehensive Assessment of Spoken Language* (CASL; Carrow-Woolfolk 1999), the *Clinical Evaluation of Language Fundamentals, Fourth Edition* (CELF-4), the *Group Reading Assessment and Diagnostic Evaluation* (GRADE; Williams 2001), and the EVT. Results indicated that the EVT-2 was moderately to highly correlated with these other measures, providing evidence that it is a valid measure of language skill.

The performance of 12 special populations on the EVT-2 was also reported. These populations included children or adults with speech impairment, young children with language delay, children or adults with language disorder, children with hearing impairment (divided into those with and without cochlear implants), and children with either learning disability (reading), mental retardation, emotional/behavioral disturbance, attention deficit disorder, or giftedness. Each group's mean score fell above, at, or below the mean as would be expected based on group membership, suggesting that the EVT-2 is a sensitive measure of vocabulary skill in special populations. The manual does not provide sensitivity or specificity data for diagnostic classification, which is considered to be the gold standard when using assessment tools for diagnostic purposes (Spaulding et al. 2006). Moreover, the average score for children with language delay or disorder fell within one standard deviation of the mean. Therefore, the results of the EVT-2 alone should not be used for making diagnostic decisions about language delay or disorder.

Clinical Uses

The EVT-2 is a quick assessment of expressive vocabulary skill and word retrieval for children and adults who speak Standard American English. In addition, the EVT-2 is sensitive to age-related changes in vocabulary skill and discriminates among special populations. Several qualitative interpretations are also available (although no evidence for the validity of these interpretations is provided). The EVT-2 was co-normed with the PPVT-4, so comparisons between expressive and receptive vocabulary can be made if both assessments are administered. The optional software program, ASSIST, provides group and individual reports in addition to evidence-based intervention ideas. Overall, the EVT-2 appears to be a psychometrically sound assessment of expressive vocabulary. However, given that data on classification accuracy for children with language delay or disorder were not provided, caution should be taken in using the EVT-2 for diagnostic classification.

The EVT-2 included 4 individuals with autism in its norming sample, or 0.2%, which was reflective of the prevalence of autism in the 2004 US population. It is unknown if individuals included in the other special population groups (e.g., language disorder, mental retardation) may have been on the autism spectrum. If both the PPVT-4 and EVT-2 are administered to a client, a higher expressive than receptive vocabulary score (i.e., EVT-2 > PPVT-4) could be an indicator of ASD (Paul et al. 2008).

Extended School Year

Brian Reichow^{1,2} and Fred R. Volkmar³

¹Child Study Center, Yale University School of Medicine, New Haven, CT, USA

²Anita Zucker Center for Excellence in Early Childhood Studies, University of Florida, Gainesville, FL, USA

³Child Study Center, Irving B. Harris Professor of Child Psychiatry, Pediatrics and Psychology, Yale Child Study Center, School of Medicine, Yale University, New Haven, CT, USA

The traditional (in the USA) 9-month academic year can present challenges to children needing ongoing support. In the past, parents frequently had to arrange a patchwork of supports over the summer months. However, for children with disabilities that qualify them for an IEP who may be in demonstrable need of ongoing services, **extended school year (ESY)** services are available. These services are designed to support a student with a disability as documented under the Individuals with Disabilities Education Act (IDEA) to maintain the academic, social/behavioral, communication, or other skills that they have learned as part of their Individualized Education Program (IEP) or Section 504 accommodation plan. These services are outlined in the IEP and are provided at no charge to parents. For children on the autism spectrum, these services often include ongoing speech-communication, special educational supports, occupational and physical therapy, and so forth.

It is emphasized that in order for a student to receive ESY services, the student must have evidenced substantial regression and recoupment issues during the previous IEP year and/or there is evidence of emerging skills, which are often

referred to as “breakthrough” skills. The focus of the services provided to the student as part of an ESY program is generally not upon learning new skills or “catching up” to grade level, but rather to provide practice to maintain previously acquired or learned skills. In some cases, ESY is focused on continuing education for students whose rate of progress is insufficient to enable effective progress during the regular school year. If a student has received ESY services in previous years, the student may not be eligible in future years as determinations for eligibility of ESY services are made annually by the IEP or 504 plan (which includes the parent and student of age 16 or older. *Note:* The mandatory age at which a student must be included varies by State but the Federal law states no later than age 16.).

Some children with autism may lose skills that they have learned (e.g., regress) if not provided with continuous programming (i.e., they regress over the long traditional summer vacation from school). Extended school year services (often referred to simply as ESY) can include both classroom-based services and related services such as occupational or speech therapy. These special services are not simply the same as summer school or summer enrichment programs and indeed are not solely limited to summer, e.g., other periods might also be appropriate. Any student receiving special education may be eligible for such services although the need, for a specific child, is determined by his or her IEP team (which includes the parents).

It should also be noted that the simple provision of a “summer program” or “summer school” is not a simple way to meet the requirements for an extended school year. That is, ESY are individualized and based on the specific programmatic needs of the individual child, whereas general summer enrichment or remedial programs are not typically individualized.

In the USA, under the IDEA mandate, these services must meet acceptable state standards and be individualized to meet each child’s specific needs. Many of the mandates/guidelines in the area have evolved based on legal decisions. Criteria frequently used to determine need include, but are not limited to, the child’s current

rate of progress, interfering behavioral concerns, opportunities to master emerging skills, the likelihood of regression, and the time that it might take the child to regain skills that would be lost.

It is sometimes the case that schools (often private special needs school) provide a full year of service with an IEP in place for the entire period. In such cases, ESY services would not be required.

Extinction Procedures

Mary Jane Weiss and Samantha Russo
Institute for Behavioral Studies, Endicott College,
Beverly, MA, USA

Definition

Extinction refers to the process of discontinuing the reinforcer that historically follows a behavior (Cooper et al. 2007).

Historical Background

In operant psychology, behavior is influenced by both the stimuli that occur prior to and following it. The stimuli that follow behaviors are consequences. Consequences influence behavior in three ways – consequences can increase (strength rate, frequency, etc.), decrease, or have no influence on strength. A reinforcing consequence results in an increased strength (or frequency or rate) of that behavior. Similar to the presentation of a reinforcer strengthening a behavior, removal of the reinforcer (or preventing it from occurring) that follows a behavior will have a weakening effect on that behavior; it will reduce in strength (or frequency or rate).

Historically, the treatment of challenging behaviors that interfere with developing independence or adaptive skills has focused on the application of punitive consequences that reduce or eliminate the target behavior. It has always been true that extinction is also relevant in this context. Over the past 15 years, the use of extinction has been explored as an alternative to aversive treatments and has been shown to effectively reduce behavior under certain conditions.

Current Knowledge

Extinction is withholding of reinforcement that typically follows a behavior and that served to maintain the behavior. However, the actual form that an extinction procedure will follow depends upon the form of the reinforcement that will be withheld. The reinforcers that maintain aberrant behaviors are not uniform or singular; behaviors serve different functions and are maintained by multiple potential effects. Sometimes, a behavior will lead to the acquisition of desirable consequences, such as access to attention, desired objects, preferred activities, or internal, physiological (e.g., sensory) stimulation. Consider a child who acts out in class to obtain teacher attention. The child engages in disruptive behavior in order to garner teacher attention. (In fact, teachers must often attend to such disruptions to ensure minimal intrusion into the flow of instruction.)

In this case, an extinction procedure would involve the teacher ignoring the behavior or in a similar case, consider a child who aggresses in order to obtain a toy or other preferred object. The child may aggress against a sibling and then gain access to a preferred toy. In this case, extinction would consist of preventing the child from obtaining that object contingent on aggression. Another example would be a child who acts out in order to get a preferred activity. For example, consider a child who is on the playground and, when told by the teacher that recess is ended and the child must go back inside, throws tantrums and cries. Historically, it could be the case that this behavior leads to more time on the playground. For example, the teacher might cajole the child, offer 5 more minutes, give several transition warnings, etc. An extinction procedure would consist of the teacher preventing the child from remaining on the playground. Instead, the child would be made to come inside.

Some behaviors exhibited by persons with autism are labeled as “self-stimulatory,” due to the belief that these behaviors are reinforced immediately by specific sensory input. For example, a child might wave her hand in front of her face because the visual movement is highly desired. These behaviors are also termed as “automatically reinforcing” behaviors because of their inherent sensory consequences that are presumably maintaining the behavior. Extinction in this type of example would require that the sensory input that the individual finds highly desirable is identified and prevented from happening. For example, Rincover et al. (1979) used extinction to stop the self-stimulatory behaviors of young children. One boy engaged in spinning plates on a table and enjoyed listening to the sound they made. The extinction procedure consisted of carpeting the surface on which he spun the plate. The carpet masked the sound, and thus plate spinning stopped. Another child engaged in flipping a light switch on and off, presumably for the visual feedback of the light. The extinction procedure for this behavior consisted of disconnecting the switch from the electrical source. From that point on, the behavior of flipping the switch produced no visual consequence, and the behavior eventually

stopped. In such sensory extinction procedures, the feedback is either reduced or eliminated, and the behavior diminishes.

With other situations, the reinforcement for a behavior could be the escape or avoidance of an aversive situation. Consider a child who throws tantrums when presented a difficult task. Historically, the tantrum is reinforced by the removal of the task. (A teacher may react to the tantrum by removing the task, changing the task, providing a break, etc.) Thus, in this particular example, the extinction procedure would involve the prevention of the termination of the task; that is, extinction in this case would consist of the teacher continuing to present the task, so that the child learns that throws tantrums will not be reinforced by task removal. An example of the well-documented use of escape extinction is in food refusal and food selectivity interventions (Dawson et al. 2003; LaRue et al. 2011; Patel et al. 2002; Piazza et al. 2003).

As noted above, if the behavior is followed by the *presentation* of a reinforcer, such as attention, preferred activities, or objects, then extinction is implemented by preventing the delivery of those reinforcing consequences or terminating them as soon as possible. On the other hand, if the behavior is reinforced by the cessation of something unpleasant (consider a child asked to do a difficult work task who has learned that a tantrum will cease the work demand), then extinction requires the continued presentation of the unpleasant stimulus. In the work demand case, extinction would require that the teacher continually present the work demand and make sure that no escape or avoidance of the task is possible. The teacher would be sensitive to even small ways in which escape could be reinforced. For example, a delay in the representation of the instruction or a brief pause in instruction could reinforce escape-motivated behavior.

Thus, it is important to understand that extinction is a procedure that prevents the reinforcement – that has typically followed a behavior – from occurring. However, since there are different types of reinforcement for behavior, the actual procedures for implementing extinction may vary.

Research on extinction has identified several effects of this process. One effect, which has been shown to generalize across response classes and settings, is a gradual decrease in rate, frequency, or intensity of behavior. Although the behavior that is extinguished will eventually return to baseline (i.e., pretreatment) levels or be eliminated altogether, the rate of decrease is slow. If a behavior is extremely severe and immediate cessation is imperative, extinction may not be the best procedure to select.

Concomitant with this gradual decrease is what is termed an “extinction burst,” a sudden increase in strength (frequency, rate, and/or intensity) of that behavior. Problem behaviors could worsen before they reduce. For example, with a young child who is crying at bedtime, parents reentering the room to comfort the child and then exiting often intensify the screaming. It may lead to escalations of the behavior and new forms of behavior during the burst that evening, and future nights may be characterized by even higher levels of the behavior. Essentially, the parents going back into the bedroom to comfort the child may reinforce screaming when being put to bed at night. Once the parents stop reentering the room, the crying may increase in both frequency and intensity for a short while. When the burst occurs, it is likely a confirmation that the controlling reinforcer has in fact been identified and successfully withheld following the occurrence of the response. If the extinction plan stays in effect, the behavior will once again reduce in strength, but some variations of an extinction burst may occur for several sessions once an extinction plan is put into place. In other words, there could be several days with some variability before the behavior is extinguished.

A phenomenon commonly associated with extinction is that of “spontaneous recovery.” The behavior is likely to recur the next day after the first day of using extinction even though the reinforcement for that behavior is no longer occurring. When this happens, the typical response is to maintain the implementation of extinction. Each day that goes by, the spontaneous recovery will be a little less, and eventually the behavior will no longer occur. This can also

happen after a behavior has been successfully extinguished, even in the absence of new reinforcement for the behavior. This can be very confusing for parents and teachers. Generally, however, spontaneous recovery is short-lived and consistent implementation of extinction will successfully address the issue.

To implement extinction, the following conditions must be met. First, the behavior must be clearly defined so that all caregivers and interventionists know when it is occurring and when it is not. Second, there should be some preextinction data on the level of the behavior, against which postextinction data can be compared, to determine if the extinction program is having the reductive effect that is intended. Third, all reinforcers that maintain the behavior must be clearly identified. This will likely require conducting a functional assessment or preferably a functional analysis (i.e., systematic manipulation of potential consequences). Fourth, a plan for either terminating the reinforcer when it occurs, or preventing it from occurring in the first place, must be developed. This is often the most difficult part of implementing extinction. Often the reinforcer is identified but with little ability to prevent it from occurring. For example, consider a child who teases other peers in his classroom for attention. The teachers may correctly identify the reinforcer as attention of the other children, but there may be a huge difficulty (and ethical considerations) in preventing all of the children in the classroom from attending to the misbehavior. If alternate sources of reinforcement remain available for the target behavior, extinction is not likely to be successful. Fifth, the people who will implement the extinction plan must consider whether they will be able to continue the extinction plan when the extinction burst occurs. Consider the following scenario – a child with autism has a history of throwing tantrums violently when a difficult work task is presented. His teacher is confident that the escape from the work demands is reinforcing the tantrum. The teacher develops a plan for continually presenting the work (i.e., making sure the work demands do not cease). However, the teacher also considers how much more violent the throws tantrums may become during the

extinction burst. For extinction to work effectively, the plan must be put into place upon the occurrence of the target behavior, regardless of the severity of the extinction burst. The teacher and other implementers must plan on how to react to the possible increase in frequency and intensity. If a child is likely to engage in topographies of behavior that are unacceptable and not ignorable (e.g., throwing desks, self-injury), extinction is not an appropriate choice.

Finally, the implementers must consistently withhold the reinforcers each time the target behavior occurs. This is one of the most difficult parts of implementing extinction, and it is one of the more critical aspects of the procedure. Failure to implement extinction contingent upon each occurrence will result of the target behavior being reinforced occasionally, which is intermittent reinforcement. Research has shown that behaviors that are intermittently reinforced are much more difficult to extinguish than behaviors on a continuous schedule. So, when implementing extinction, failure to withhold reinforcement for each behavioral occurrence could likely result in the behavior becoming even stronger in the person's repertoire. If some reinforcement is likely to occasionally occur, extinction may not be the best method to select.

Good practice suggests that extinction be implemented in combination with other procedures, such as differential reinforcement of other behaviors, noncontingent reinforcement, or differential reinforcement of alternative behaviors. Research suggests that when used in combination, extinction may increase the effectiveness of other procedures. Additionally, the use of reinforcement procedures to strengthen appropriate behaviors is part of best clinical practice.

Future Directions

Extinction is considered a treatment for problem behaviors that is not aversive and acceptable to most staff. It is not as regulated as other more intrusive procedures, such as time-out or over-correction. Although researchers have investigated the role of clinical treatment with and without implementing extinction procedures, the

results remain ambiguous. Identification of behavior classes and/or environmental conditions under which extinction is necessary or optimal in clinical application would be helpful. Clinically, it is important to match the procedure of extinction to certain behavioral characteristics and learners. Clinicians must be mindful of controlling all sources of reinforcement and of monitoring behavioral escalations in bursts.

Extreme Male Brain (EMB) Theory

Bonnie Auyeung¹, Michael Lombardo¹,
Rebecca Knickmeyer² and Simon Baron-Cohen¹
¹Autism Research Centre, University of
Cambridge, Cambridge, UK
²Department of Psychiatry, University of North
Carolina, Chapel Hill, NC, USA

Definition

Autism spectrum conditions (ASC) have been described as an extreme manifestation of certain traits or as a consequence of an “extreme male brain.”

Historical Background

The link between ASC and “maleness” was first proposed by Hans Asperger in his 1944 clinical account where he states, “The autistic personality is an extreme variant of male intelligence. . . In the autistic individual the male pattern is exaggerated to the extreme.” More recent evidence has led to the proposal that ASC may be an exaggeration of certain male-typical characteristics (Baron-Cohen 2002; Baron-Cohen et al. 2005).

Current Knowledge

Autism spectrum conditions (ASC) are characterized by impairments in social interaction and communication, alongside unusually restricted, repetitive, stereotyped patterns of behavior, interests, and activities. The American Psychiatric Association uses the term ASD for autism spectrum disorders. The term ASC will be used as those at the higher-functioning end of the autistic

spectrum do not necessarily see themselves as having a “disorder,” and the profile of strengths and difficulties in ASC can be conceptualized as atypical but not necessarily disordered. ASC remains a medical diagnosis, hence the use of the term “condition,” which signals that such individuals need support. Use of the term ASC recognizes that the profile in question does not fit a simple “disease” model but includes areas of strength (e.g., in attention to detail) as well as areas of difficulty and does not identify the individual purely in terms of the latter.

Approximately 1% of children have a diagnosis of ASC. These conditions have a strong neurobiological and genetic component. There is also a clear male to female ratio in the incidence of ASC, estimated at 4:1 for classic autism and over 10:1 in individuals with Asperger syndrome. The cause of the male bias in ASC is not fully understood. Many clinical conditions occur in males more often than females, including autism, dyslexia, specific language impairment, attention-deficit/hyperactivity disorder (ADHD), and early-onset persistent antisocial behavior. Depression, anorexia, and the anxiety disorders show a female bias in sex ratio, raising the question of whether there are sex-linked or sex-limiting factors involved in the etiology of conditions that exhibit a male bias.

ASC in particular have been described as an extreme manifestation of certain sexually dimorphic traits or as a consequence of an “extreme male brain” (EMB) (Baron-Cohen 2002; Baron-Cohen et al. 2005). Individuals with ASC have been shown to be impaired in empathy (the drive to identify another person’s emotions and thoughts, and to respond to these with an appropriate emotion and an area where females show an advantage), while being average or even superior in systemizing (the drive to analyze, explore, and construct a system and an area males show an advantage).

Studies of Empathy and Systemizing

It is widely accepted that males and females show significant differences in their neuroanatomy,

cognition, and behavior from an early age. Sex differences in the precursors of empathy are seen from birth, with female babies on average showing a stronger preference for looking at social stimuli (faces) from 24 h after birth (Connellan et al. 2000). Girls have also been found to make more eye contact immediately after birth (Hittelman and Dickes 1979), at 12 months of age (Lutchmaya et al. 2002a) and at 2 and 4 years of age (Podrouzek and Furrow 1988). Girls on average also exhibit more comforting, sad expressions or more sympathetic vocalizations when witnessing another’s distress (Hoffman 1977). Girls on average also show better quality of social relationships at 48 months, as measured by a subscale of the Children’s Communication Checklist. Similar patterns have been observed in adults, with women on average being more likely to report more intimate relationships, having a confidant and receiving social support and visits from friends and family (Baron-Cohen and Wheelwright 2003).

Using measures that directly assess aspects of empathy, girls are on average better than boys at evaluating the feelings and intentions of characters in a story (Bosacki and Astington 1999) and differentiating between the appearance and reality of emotion (Banerjee 1997). There is also a female superiority on the “faux pas” test of social sensitivity (Baron-Cohen et al. 1999) which measures the recognition of someone saying something that might be hurtful. Sex differences in empathy remain evident in adulthood: for example, women on average score higher than men on the “Reading the Mind in the Eyes” test, which examines subtle mental state and emotion recognition (Baron-Cohen et al. 2001).

In general, studies have shown that individuals with ASC are also impaired on empathy-related tasks that normally give rise to female superiority, such as the “Social Stories Questionnaire” (Lawson et al. 2004), the “Reading the Mind in the Eyes” task (Baron-Cohen et al. 2001), and the recognition of “faux pas” in short stories (Baron-Cohen et al. 1999). Adults with ASC score lower on the Friendship and Relationship Questionnaire, which assesses empathic styles of relationships (Baron-Cohen and Wheelwright 2003).

Children with autism perform less well than controls on the “Feshbach and Powell Audiovisual Test for Empathy,” a measure of empathy and emotional responsiveness (Yirmiya et al. 1992). Children with ASC also show more difficulties passing “theory of mind” tests compared to typically developing children (Happé 1995).

Studies examining play preferences point toward more interest in mechanical and constructional play in boys, demonstrated by a preference to play with toy vehicles or construction sets, while girls are more likely to choose to play with dolls or toy animals (Berenbaum and Hines 1992). Males on average also score higher on tasks that require systemizing such as using directional cues in map reading and map making (Kimura 1999), intuitive physics (Lawson et al. 2004), and the SAT Math Test (Benbow and Stanley 1983). They are also more accurate on measures of spatial ability such as mental rotation and spatial visualization (Voyer et al. 1995). Finally, males on average score higher on the Embedded Figures Test (EFT) (Witkin et al. 1962), which measures attention to detail and field independence – both prerequisites for systemizing (Baron-Cohen 2002).

Experimental evidence supporting the EMB theory of autism includes findings that individuals with ASC tend to show superior performance compared to typical controls on tasks that involve systemizing and on certain visuospatial tasks that normally give rise to male superiority, such as figure disembedding (Falter et al. 2008; Jolliffe and Baron-Cohen 1997; Ropar and Mitchell 2001; Shah and Frith 1983), block design (Ropar and Mitchell 2001; Shah and Frith 1993), and mental rotation (Brosnan et al. 2009; Falter et al. 2008).

Brosnan et al. (2009) suggest that mental rotation tasks can be separated into rotational and non-rotational components and observed a significant correlation between systemizing and the non-rotational components of the mental rotation task but not the rotational component of the task (Brosnan et al. 2009). Individuals with high-functioning autism (and therefore intact IQ) have also been observed to demonstrate superior accuracy and shorter learning times in tasks that involve maps (Caron et al. 2004).

A recent study by Pierce et al. (2010) found that toddlers with an ASD as young as 14 months spent significantly more time fixating on dynamic geometric (“systemizable”) images, whereas typically developing toddlers showed longer looking times at social stimuli. Further, if a toddler spent more than 69% of his or her time fixating on geometric patterns, then the positive predictive value for accurately classifying that toddler as having an ASD was 100% (Pierce et al. 2010). These findings suggest that these early looking preferences can be found very early in life and used to differentiate toddlers with ASC from typically developing toddlers.

However, the EMB theory has not been shown to apply to all measures showing a male advantage. For example, Falter et al. (2008) found that children with autism do not show superior performance on a measure of targeting ability compared to typically developing boys. It is possible that problems with motor coordination (dyspraxia) in the ASC group may have affected performance on this task. It is worth emphasizing that the EMB theory predicts intact or superior performance on measures of systemizing in ASC and that the EMB theory does not focus on systemizing alone, but on the discrepancy between an individual’s empathy and systemizing abilities.

The Empathy Quotient (EQ) and Systemizing Quotient (SQ)

The Empathy Quotient (EQ) and Systemizing Quotient (SQ) were developed in order to examine trends in gender-typical behavior in adults. The EQ and SQ are self-report questionnaires with a Likert format and contain a list of statements about real-life situations, experiences, and interests where empathizing or systemizing skills are required. Findings from the EQ in adults revealed a significant sex difference, with women scoring significantly higher than men. Results from the SQ indicate that men score significantly higher than women (Carroll and Chiew 2006; Wheelwright et al. 2006). A parent-report version of the EQ and SQ for children between 4 and 11 years of age has also shown similar results with girls scoring significantly higher on the EQ and boys scoring significantly higher on

the SQ (Auyeung et al. 2009c), suggesting that these patterns are present from an early age.

In adults, EQ and SQ scores have also been shown to be better predictors than sex for career choice in science and engineering, or in degree choice (e.g., science vs. humanities), suggesting that typical sex differences in interests or aptitudes may reflect the individual’s cognitive style, independent of their sex.

In order to compare an individual’s empathizing and systemizing, Goldenfeld et al. (2005) examined standardized (normalized) scores on the EQ and SQ. The differences between standardized scores demonstrated strong sex differences and led to the definition of empirical “brain types.” The five “brain types” describe whether an individual is “balanced” (Type B), better at empathizing (Type E), or better at systemizing (Type S). “Extreme” empathizing (Extreme E) or systemizing (Extreme S) types were also assigned where an individual showed a significant discrepancy in different directions (Goldenfeld et al. 2005; Wheelwright et al. 2006). The assignment of “brain types” based on relative EQ and SQ scores in both children and adults appears to be a useful method of describing differences in sex-typical behavior, with the majority of females toward Type E and the majority of males toward Type S (Auyeung et al. 2009c; Goldenfeld et al. 2005; Wheelwright et al. 2006).

Findings using the EQ and SQ questionnaires also provide further evidence for the EMB theory of ASC. When the scores obtained from the EQ and SQ are standardized using the method suggested by Goldenfeld et al. (2005), the vast majority of children and adults with high-functioning autism or Asperger syndrome are found to show the Type S or Extreme S “brain types” (Auyeung et al. 2009c; Goldenfeld et al. 2005; Wheelwright et al. 2006). See Table 1 for a summary of psychological evidence that – irrespective of the direction of sex difference – people with autism show an extreme of the male profile Table 2.

In addition to the evidence at the behavioral level, it has been suggested that characteristics of neurodevelopment in autism such as larger overall brain volumes and greater growth of the amygdala during childhood may also represent an exaggeration of typical sex differences in brain development (Baron-Cohen et al. 2005). Studies using fMRI indicate that typical females show increased activity in the extrastriate cortex during the Embedded Figures Test and increased activity bilaterally in the inferior frontal cortex during the “Reading the Mind in the Eyes” task. Parents of children with ASC also tend to show hyper-masculinization of brain activity, suggesting that hyper-masculinization may be part of the broader autism phenotype.

Extreme Male Brain (EMB) Theory, Table 1 A summary of the psychological evidence for the extreme male brain (EMB) theory

Psychological measure	Autism > male > female	Female > male > autism
Adult systemizing quotient (SQ)	✓	
Child SQ	✓	
Embedded figures test	✓	
Intuitive physics test	✓	
Adult autism spectrum Quotient (AQ)	✓	
Adolescent AQ	✓	
Child AQ	✓	
Childhood autism spectrum Test (CAST)	✓

The Role of Social Factors in the Development of Sex Differences

Social interactions undoubtedly play an important role in the development of gender-typical play and toy choices. Gender-based expectations may cause parents, teachers or caregivers to elicit and reinforce expected behavior from children (Stern and Karraker 1989), thus shaping the child’s behavior. It has been shown that infant gender labeling as male or female often elicits sex-stereotypic responses from adults and children (Stern and Karraker 1989). It has also been suggested that girls are encouraged to be more sensitive and caring toward others than boys (Gilligan 1982). Findings from studies examining play preferences have indicated that boys are encouraged by parents to play with masculine-typical toys and discouraged from playing with feminine-typical toys (Fagot and Hagan 1991). Girls, on the other hand, are also encouraged to play with feminine-typical toys but not necessarily discouraged from playing with masculine-typical toys (Fagot and Hagan 1991). While these factors might influence the behavior exhibited by typically developing children, studies examining eye contact and preference for social stimuli in newborn children provide convincing evidence for a biological basis for some sex differences. It is also not clear how such social factors might apply to the ASC group.

The Role of Prenatal Hormones in the Development of Sex Differences

Though genetic sex is determined at conception, it is the gonadal hormones (i.e., androgens, estrogens, and progestins) that are responsible for differentiation of the male and female phenotypes in the developing human fetus. It is thought that behaviors showing large sex differences are the best candidates for studying effects of hormones on later development (Hines 2004). The direct sampling of fetal serum or manipulation of fetal hormone levels would be highly dangerous. As a result, researchers have employed indirect methods of measuring prenatal hormone exposure to study effects on later development.

One such indirect measure is the ratio between the length of the 2nd and 4th digit (2D, 4D) of the hand. This ratio has been found to be sexually dimorphic, being lower in males than in females. 2D:4D ratio is thought to be fixed by week 14 of fetal life and has been found to reflect fetal exposure to prenatal sex hormones in early gestation (Lutchmaya et al. 2004; Manning 2002). Results from studies of 2D:4D ratios as proxies for fetal testosterone (fT) levels show that children with ASC have more masculinized digit ratios compared to typically developing boys. These patterns have also been observed in the siblings and parents of children with ASC, indicating the possibility of a link between genetically based elevated fT levels and the development of ASC (Manning et al. 2001).

The medical condition of Congenital Adrenal Hyperplasia (CAH) leads to abnormally high prenatal and neonatal androgen levels and has provided researchers with an indirect method of examining the effects of elevated androgen exposure. Girls with CAH have more autistic traits (measured using the adult AQ) compared to their unaffected sisters (Knickmeyer et al. 2006a). Given that this condition is usually treated following birth, this suggests their higher AQ scores reflect elevated prenatal androgen levels. These findings should be interpreted with caution, however, since CAH carries a number of related problems (as well as extensive treatment) which may affect the atypical cognitive profiles found in this population.

Some studies have also compared measurements of testosterone in umbilical cord blood with postnatal development. A recent study using umbilical cord blood testosterone measures examined pragmatic language ability in girls followed-up at 10 years of age. Results showed that the higher a girl’s free testosterone level at birth, the higher the scores on a pragmatic language difficulties questionnaire (Whitehouse et al. 2010). However, levels of fT are typically at very low levels from about week 24 of gestation, umbilical cord samples can contain blood from the mother as well as the fetus, and hormone levels may vary due to labor itself, so umbilical cord blood testosterone does not allow one to test if outcomes reflect fT per se.

Currently the best method to examine the effect of fT is to sample the amniotic fluid surrounding the fetus via amniocentesis. An advantage of amniotic fluid samples is that amniocentesis is often performed for routine clinical purposes within a relatively narrow time period which coincides with the hypothesized critical period for human sexual differentiation between weeks 8 and 24 of gestation (Hines 2004). This is also more direct than the 2D:4D method as the hormones themselves can be assayed, rather than relying on a proxy for these.

A number of studies have linked elevated levels of fT in the amniotic fluid with the masculinization of certain behaviors, beginning shortly after birth. Elevated fT has been linked to reduced

eye contact in infants (Lutchmaya et al. 2002a), smaller vocabulary in toddlers (Lutchmaya et al. 2002b), narrower interests and poorer quality of social relationships at 4 years of age (Knickmeyer et al. 2005), less empathy at 4 and 8 years (Chapman et al. 2006; Knickmeyer et al. 2006b), more male-typical play behavior (Auyeung et al. 2009a), better performance on the Children’s Embedded Figures Test (Auyeung et al., in press), and increased systemizing at 8 years (Auyeung et al. 2006). In addition, fT levels have been found to be positively correlated with number of autistic traits (measured using the Quantitative Checklist for Autism in Toddlers (Allison et al. 2008)) in toddlers between 18 and 24 months of age (Auyeung et al. 2010), as well as in older children (ages 6–10 years old), using two independent dimensional measures of autistic traits (the child version of the AQ and the Childhood Autism Spectrum Test (Auyeung et al. 2009b)). Evidence from typically developing children for effects of fT is summarized in Table 3.

The use of amniotic fluid to measure prenatal hormonal exposure has several limitations. Ideally, it would be best to make direct measurements of testosterone at regular intervals throughout

Extreme Male Brain (EMB) Theory, Table 3 Evidence from typically developing children for effects of fT

Evidence from typical children	Key references

gestation and into postnatal life. However, it would be extremely hazardous to attempt direct measurements from the fetus itself for purely research purposes. It is not possible to obtain repeated samples of fT because amniocentesis itself carries a risk of causing miscarriage (of about 1%). As a result, obtaining amniotic fT measures are opportunistic, when the procedure is being carried out for clinical reasons, with never more than a single measurement of fT at one time-point although it is known that hormones fluctuate during the day and between days, even in fetuses. The representativeness of a single sample of fT thus remains unclear, but would be difficult to explore in an ethical manner.

In addition, given the reported time course of testosterone secretion, the most promising time to measure fT is probably at prenatal weeks 8–24 (Smail et al. 1981), but this is still a relatively wide range. In addition, research in nonhuman primates has shown that androgens masculinize different behaviors at different times during gestation, suggesting different behaviors may also have different sensitive periods for development. For all these reasons, the inferences that can be drawn about a single measurement of fT are therefore limited. However, where a significant correlation between amniotic fT and a behavior is observed, this should represent a very conservative estimate of the correlation between overall fT levels and that behavior.

Evidence Implicating Testosterone in the Etiology of Autism

Genetic influences are undoubtedly involved with other factors (such as prenatal hormone levels) which lead to the development of ASC. Evidence of a genetic link to ASC is provided by a recent study which shows that genes regulating sex steroids are associated with autistic traits, as measured by scores on the Autism Spectrum Quotient (AQ), in a typical adult sample (Chakrabarti et al. 2009). A parallel study also showed that genes regulating sex steroids are associated with a diagnosis of Asperger syndrome in a case-control sample (Chakrabarti et al. 2009).

<i>Testosterone related characteristics</i> in women with ASC and their mothers	Ingudomnukul et al. (2007), Knickmeyer et al. (2008)
<i>Lower 2D:4D ratio</i> in ASC, and parents	Manning et al. (2001), Milne et al. (2006), Noipayak (2009)
<i>SRD5A1, and AR genes</i> associated with ASC	Henningssson et al. (2009), Hu et al. (2009)

Other lines of evidence implicating testosterone in the etiology of ASC are summarized in Table 4:

Conclusions

There is a significant body of evidence connecting the characteristic behaviors of ASC to extremes of certain male-typical behaviors. Evidence includes superior performance on a range of tasks where males typically outperform females but impairment compared to typical males on tasks showing a female advantage. This observation has led to the development of the “extreme male brain” theory of autism. Support for this theory can also be found very early in life, and also in some primate studies suggesting the development of sex-typical behaviors is at least partly biological.

Research using direct measures of potential biological factors such as prenatal hormones as well as multiple measures of empathizing and systemizing, including both observational and behavioral measures are needed to explore the link between these factors in greater detail. Although the findings presented in this chapter lend support to the “extreme male brain” theory of ASC and its link to fT, a thorough evaluation of this theory will require testing not just for associations between fT and autistic traits, but between fT and clinically diagnosed ASC. This remains an active area of research.

Future Directions

Future studies of empathizing and systemizing in children could examine whether the relationships between fT levels (and other biological factors) remain consistent using multiple measures of empathy and systemizing (e.g., observational, experimental). In addition, the replication of the findings related to fT levels in larger sample sizes would assist in identifying any factors that are linked with levels in the extreme ranges. Future studies could assess whether relationships between fT levels and the development of autistic traits are consistent for individuals with a clinical diagnosis of ASC since the current samples only included typically developing children. Considering the current support for a role for fT in the development of autistic traits, it would also be beneficial for future studies to examine the relationships between fT levels, genetic variation, and the development of autistic traits.

The EMB theory of autism has been developed from studies in typically developing and high-functioning individuals with ASC. It would be interesting to extend the scope of this theory with an examination of individuals with more severe forms of ASC. It is also important to assess the validity of “empathizing” and “systemizing” measures by correlating these with performance and everyday measures of functioning, and future studies could further explore how these domains develop and also how they correlate with neural structure and function.

Eye Contact

► Mutual Gaze

Eye Gaze

Atsushi Senju

Centre for Brain and Cognitive Development,
Birkbeck, University of London, London, UK

Definition

The term “eye gaze” may refer to either of the two distinctive, but related, topics. Firstly, it refers to the perception of other persons’ eye gaze, which can be inferred from the relative position of the iris within the eyelid, in conjunction with the orientation of the head and the body. Secondly, it also refers to the production of eye gaze by a patient or a participant, such as the control of saccades and fixations. This entry mainly covers the former topic. Perception of others’ eye gaze is crucial for social interaction and communication and its impairment in ASD because eye gaze signals the direction of others’ attention and intention.

Current Knowledge

Fixations on Another Person’s Eyes

Atypical pattern of mutual gaze behavior, or eye contact, is among the most distinguishable manifestation of the qualitative impairment in social interaction in ASD. Since Kanner’s first report (Kanner 1943), such atypical pattern of eye contact has been reported and discussed in many clinical and experimental settings, including recent studies using eye-tracking methods (Senju and Johnson 2009a). Based on this clinical significance, eye contact is currently included in standardized diagnostic criteria such as DSM and ICD. In DSM-IV-TR, it is defined as a “marked impairment in the use of multiple nonverbal behaviors (e.g., eye-to-eye gaze) to regulate social interaction and communication” (American Psychiatric Association [APA] 2000, p. 70). Retrospective home video analyses of infants who were

later diagnosed with ASD have revealed that atypical patterns of eye contact can be observed within the first year of life, well before the age of diagnosis (Maestro et al. 2005). Some researchers and clinicians once proposed that such atypical eye contact behavior results from “gaze avoidance,” active avoidance of others’ eye gaze due to negatively valenced overarousal (e.g., Hutt and Ounsted 1966). However, follow-up studies reported mixed results, suggesting that the gaze avoidance may be present in some individuals with ASD, but it may not be universal or predominant in this population (Buitelaar 1995).

Some of eye-tracking studies have revealed that individuals with ASD fixate others’ eyes less than typically developing individuals do, but other studies failed to replicate or reported mixed results (Senju and Johnson 2009a). Such inconsistencies may result from the differences in task demands and/or the characteristics of stimuli used. In general, reduced fixations on the eyes are most prominent with complex and cognitively demanding face stimuli and/or by using dynamic videotape stimuli, including conversations. Moreover, individual differences in the fixations on the eyes within ASD correlate with the volume and the face sensitivity of amygdala (e.g., Dalton et al. 2005), as well as the degree of self-reported social anxiety (Corden et al. 2008). However, it does not correlate with autistic symptoms measured with ADOS or AQ (Corden et al. 2008).

Perception of Direct Gaze

Direct gaze signals that the person is looking at the perceiver. It also leads to the establishment of mutual gaze or eye contact, which signals the initiation of communication. In typically developed population, perceived direct gaze, or eye contact, modulates concurrent and/or immediately following cognitive processing and/or behavioral responses, a phenomenon called the eye contact effect (Senju and Johnson 2009b). For example, perceived eye contact facilitates the performance of face-related tasks such as gender discrimination, recognition of face identity, and detection of gaze direction. Results from neuroimaging studies

also indicate that perceived eye contact modulates the activation of social brain network (defined as the cortical and subcortical structures specialized for the processing of social information, such as fusiform gyrus, superior temporal sulcus, medial prefrontal and orbitofrontal cortex, and amygdala). Sensitivity to the direction of another person's eye gaze appears very early in typical development (Johnson et al. 2009). For example, newborns preferentially look longer at the faces with direct gaze than those with averted gaze. Perceived eye contact also facilitates the processing of face identity and communicative facial expression during the first half year of life.

A series of studies have demonstrated atypical processing of direct gaze in ASD (Senju and Johnson 2009a). For example, Senju, Yaguchi, Tojo, and Hasegawa (2003) used an oddball procedure in which children were asked to detect a rare stimulus presented occasionally within the context of a frequently reoccurring stimulus. The rare stimuli were either faces with direct gaze or those with laterally averted eye gaze (i.e., faces with eyes looking leftward or rightward). The frequent stimuli were faces with eyes looking downward. Thirteen children with autism (mean age: 12 years) were compared with typically developing children of the same range of the age and nonverbal intelligence. Typically developing children showed the eye contact effect, that they were better at detecting direct gaze than averted gaze. By contrast, although children with autism are equally good at detecting averted gaze as typically developing children, they were less skilled at detecting faces with direct gaze, and they failed to show the eye contact effect or the facilitation of performance caused by the perceived direct gaze. Similarly, Pellicano and Macrae (2009) assessed whether direct gaze facilitates the person categorization in children with autism (mean age: 10 years) and age- and IQ-matched typically developing children. Results revealed that typically developing children were faster to categorize faces by sex when they were with direct gaze than with averted gaze. By contrast, although children with autism were as fast as typically developing children to categorize faces, their performance were unaffected by the gaze direction of the faces. These studies

demonstrate that unlike typically developing individuals, individuals with ASD do not show the eye contact effect or the facilitation of face and gaze processing caused by the perceived direct gaze.

Several studies have recorded field potentials on the scalp with either EEG or MEG to assess the cortical response to direct and averted gazes in individuals with ASD, but results are mixed. Two studies reported that 3- to 7-year-old children (mean age: 5 years, Grice et al. 2005) as well as 7- to 12-year-old children (mean age: 10 years old, Kylliäinen et al. 2006) with ASD showed larger event-related potential (ERP) or event-related field (ERF) response to direct gaze than averted gaze, but control children did not. By contrast, Senju, Tojo, Yaguchi, and Hasegawa (2005) reported that typically developing children (9- to 14-year-olds, mean age: 12 years) showed a larger ERP amplitude for direct than for averted gaze, but ERPs of children with ASD were not modulated by the presence of eye contact. Moreover, Elsabbagh et al. (2009) recorded EEG from high-risk infants (see also ► [“Early Diagnosis”](#)) as well as from low-risk control infants while they watched faces with either direct or averted eye gaze and conducted ERP and time-frequency analysis (TFA). Results showed that a late ERP component (P400), which is known to relate to face processing, has a longer latency in response to direct gaze in high-risk infants. Secondly, TFA analysis revealed clearly distinguished and temporally sustained high-frequency oscillatory activity in the gamma-band frequency for direct gaze compared to averted gaze in control infants. In contrast, high-frequency oscillatory activity in gamma band for direct gaze compared to averted gaze in high-risk infants was delayed and less persistent. These results suggest that atypical eye contact processing in high-risk infants relates to the top-down modulation (as indicated by the slower P400 latency) and task-relevant synchronization of brain activations (as indicated by the lack of differential gamma-band activation in response to eye contact).

Two studies have assessed skin conductance response (SCR), an index of physiological arousal, while individuals with ASD observe faces with either direct or averted eye gaze.

However, the results are again mixed – one study found larger SCR in response to direct gaze in 10-year-old children with ASD (Kylliäinen and Hietanen 2006), but the other study did not replicate this findings in 12-year-old children (Joseph et al. 2008). Such inconsistency between physiological studies may result from the different age ranges of the participants and/or the different experimental tasks used for EEG/MEG/SCR recordings.

To summarize, behavioral studies have consistently found that direct gaze facilitates cognitive processing of faces in typically developing children, but the face and gaze processing of individuals with ASD are unaffected by the presence of direct gaze (Senju and Johnson 2009a). Inconsistencies in the physiological studies make it difficult to understand the neural basis of such atypical processing of direct gaze in individuals with ASD.

Perception of Averted Gaze

Averted gaze, by contrast, signals that the person is looking at something in the environment. Thus, following another person's gaze helps enable the perceiver to infer his or her attention, goal, and/or intention (see also ► “Gaze”). In typical development, perceived averted gaze reflexively shifts the attention of the perceiver to the corresponding direction, which is often called gaze cueing effect (Frischen et al. 2007). The gaze cueing effect can be observed from 3 months of age, which corresponds to the age range when a rudimentary form of gaze following starts to appear.

Individuals with ASD do not have an overall impairment in detecting the direction of others' eye gaze. For example, Leekam, Baron-Cohen, Perrett, Milders, and Brown (1997) demonstrated that children with autism are as good as typically developing children at discerning the subtle differences in gaze direction. Moreover, majority of studies demonstrated that individuals with autism across the wide age range, from 2-year-old toddlers to adults, show apparently typical gaze cueing effect (Nation and Penny 2008). In these studies, participants are presented with a picture of a face with gaze averted to the left or right followed by a target stimuli presented either to the left or right of the face. Individuals with ASD, as well as typically developing individuals,

are faster to detect the target when the face was looking at the location than when the face was looking at the opposite direction. These studies contrast with the impairment in gaze following behavior in individuals with ASD (see also ► “Gaze”).

However, several studies also suggest the qualitative differences in the gaze cueing effect between individuals with ASD and typically developing individuals. For example, Senju, Tojo, Dairoku, and Hasegawa (2004) compared the cueing effect of eye gaze and an arrowhead and found that children with autism do not show preferential sensitivity to eye gaze unlike typically developing children. Other studies (e.g., Ristic et al. 2005) used a schematic face, instead of a photographic image of a face, and found that only typically developing individuals show the gaze cueing effect in response to the schematic eyes. By contrast, individuals with ASD do not show gaze cueing effect in response to these stimuli. These studies suggest that the gaze cueing effect in individuals with ASD is not as robust as in typically developing individuals and perhaps is not processed in a functionally specialized cognitive mechanism.

Individuals with ASD also show difficulties in inferring mentalistic and communicative significance of the eyes. For example, Baron-Cohen, Baldwin, and Crowson (1997) presented two novel objects to 7- to 12-year-old children with ASD as well as typically developing children matched by the mental age and verbally labelled one of these objects. Typically developing children correctly associated the label with the object being looked at by the experimenter, even when the child was looking at the other object when the experimenter uttered the label. By contrast, children with autism tended to apply the label to objects in their own focus rather than the one the experimenter was looking at. An adult neuroimaging study also demonstrated that individuals with ASD, unlike typically developing individuals, do not show differential cortical activation in response to the referential gaze (Pelphrey et al. 2005).

To summarize, individuals with ASD have relatively good capacity to encode the direction of others' eye gaze and reflexively shift their

attention to the corresponding direction. However, the gaze processing in individuals with ASD may not be as robust or specialized as those of typically developing individuals, which may be related to the difficulty in using others' eye gaze in the context of social learning.

Future Directions

Further studies will be required to clarify the neurodevelopmental basis of eye gaze processing in ASD and its relationship with other clinical symptoms. Firstly, it is not clear why there are such inconsistencies between different neurophysiological studies contrasting direct and averted gaze processing in ASD, as well as the different eye-tracking studies investigating the pattern of face scanning in ASD (Senju and Johnson 2009a). Thus, further studies will be required to systematically control the background of participants (e.g., age, gender, and/or comorbidity) as well as the properties of the stimuli and the tasks used (e.g., dynamic vs. static, active task vs. passive viewing, size and/or facial expression) to reveal the neurophysiological basis of direct gaze processing in ASD. Secondly, it will be important to investigate the relationship between atypical cortical response to eye gaze in early infancy (e.g., Elsabbagh et al. 2009) and the later manifestation of clinical symptoms.

Definition

Eye movement desensitization and reprocessing (EMDR) therapy is a first-choice psychological treatment for posttraumatic stress disorder

(PTSD) in the general population (World Health Organization 2013; ISTSS 2019). Although there is growing evidence that the scope of EMDR therapy is broader than treatment of full blown PTSD, little is known about the feasibility and potential effectiveness of EMDR in children and adults with autism spectrum disorder (ASD) who suffer from the consequences of exposure to adverse events and trauma. There are indications that these consequences often are overlooked and misinterpreted as autistic features and therefore remain untreated. This entry provides an overview of the current knowledge about the feasibility and effectiveness of EMDR therapy in individuals with ASD and trauma-related symptoms and its clinical and scientific implications.

EMDR therapy is a protocolized treatment, aimed to resolve symptoms resulting from disturbing and unprocessed life experiences. EMDR therapy is an evidence-based treatment for PTSD and may be supportive in the treatment of a wide variety of other mental health problems like anxiety disorders, depressive disorders, and obsessive-compulsive disorders (Shapiro 2018; Valiente-Gómez et al. 2017). EMDR therapy starts with history taking and a case conceptualization. Therapy continues with a short introduction about how EMDR therapy works, shortly after which the client focusses on the traumatic memory. The therapist then asks the client to bring up the memory and to focus on the most distressing image, eliciting the dysfunctional negative cognition (NC) of oneself in relation to the image, as well as the accompanying emotions and the body disturbance that go along with it. Next, the therapist moves his or her fingers back and forth in front of the client's eyes as fast as the client can follow. Repeatedly, the client is asked to report about emotional, cognitive, somatic, and/or imagistic experiences that arise. A new set of eye movements follows, and this procedure is repeated until the disturbance related to the memory reaches a SUD (Subjective Unit of Disturbances scale) of zero out of ten and an adaptive and positive statement about oneself (PC, Positive Cognition) is rated as fully believable on a VoC (Validity of Cognition) scale. The end of the session is dedicated to closing down the session positively and preparing the

client for the interim in between sessions. A core feature of the procedure is carrying out a sufficient demanding bilateral working-memory-task which is accomplished by the rapid eye movements (De Jongh et al. 2013).

Historical Background

Children and adults with ASD are at *elevated risk* of experiencing a history of adverse events and revictimization (Hoover 2015; Kildahl et al. 2019). It has been argued that exposure to adverse events inhibits the ability to detect violations and exacerbates already impaired emotion regulation problems in youth with ASD (Kerns et al. 2015). These factors may negatively influence the ability to cope with future stressors and elevate the risk of revictimization. PTSD in children and adolescents with ASD co-occurs at a similar or greater rate compared to general population estimates (Rumball 2019).

Individuals with ASD are known to have specific difficulties in resolving unprocessed life experiences, making them *susceptible to psycho-social consequences of exposure* to adverse events (e.g., Roberts et al. 2015). ASD can be characterized as a different way of sense-making and as a problem with self-regulation, which is reflected in problems in social communication and interaction and restricted and repetitive patterns of behavior or interests. Adverse events that are considered to be mildly annoying for individuals without ASD may be perceived as distressing or even traumatic by individuals with ASD and vice versa (Taylor and Gotham 2016). Wood and Gadow (2010) hypothesized that ASD-related sensory hyper-reactivity to daily stimuli, social confusion, incomprehension, and rejection by others may lead to clinically significant anxiety, which affects resilience to cope with stressors.

Several authors reported a risk of *overlooking* a history of exposure to adverse events and symptoms of PTSD in persons with ASD. There may be several reasons for this phenomenon. First, the different sense-making may prevent them from recognizing risky circumstances and

communicating about their experiences (Kerns et al. 2015). The risk of overlooking is even stronger in case of persons with ASD and an intellectual disability (Kildahl et al. 2019). Second, symptoms attributed to ASD might in fact be stress reactions to adverse events or trauma, a phenomenon termed *diagnostic overshadowing*. For example, hyper-arousal and numbing (symptoms of PTSD) overlap with ASD related hyper- and hypo-reactivity to sensory stimuli. Feelings of detachment of others – a symptom of PTSD – partly overlap with deficits in social-emotional reciprocity. A reduced ability to mentalize and recognize emotions is seen in both people with PTSD and in people with ASD. Also, there is an overlap between the ASD-related symptoms of perseveration and rumination and the criterion *negative cognitions and mood* due to PTSD (DSM-5 2013). Especially people with severe PTSD symptoms not fulfilling PTSD DSM-5 criteria (e.g., because they do not meet DSM-5 criterion A for PTSD) are at risk to be excluded for trauma treatment. Hence, both trauma and trauma-related symptoms can be overlooked or overshadowed by autistic features and therefore remain untreated.

Current Knowledge

Little is known about the feasibility and potential effectiveness of EMDR therapy in individuals with ASD and trauma-related symptoms. This may partly be caused by the problem of overlooking and overshadowing as mentioned above. Another impeding factor may be that individuals with ASD are often excluded from participating in research (Spinazzola et al. 2005). This entry gives a short overview of what is known about EMDR in autistic children and adults with and without intellectual disabilities.

EMDR Therapy in Children with ASD

Preliminary findings from a few case reports suggest EMDR therapy for PTSD to be feasible and potentially effective for children with ASD (e.g., Ipci et al. 2017) also in case of comorbid intellectual disabilities (Mevisen et al. 2011). Controlled studies are lacking.

EMDR Therapy in Adults with ASD

Several case reports have been published describing the treatment of trauma with EMDR therapy in adults with ASD (Kosatka and Ona 2014) and in adults with ASD and intellectual disabilities (Barol and Seubert 2010; Mevissen et al. 2011), with promising results.

Until now, one controlled study has been published describing the feasibility and effectiveness of EMDR therapy for PTSD symptoms in adults with ASD (Lobregt-van Buuren et al. 2019). The study investigated whether EMDR is a feasible therapy for adults with ASD and a history of adverse events and whether it is associated with reductions in symptoms of PTSD, psychological distress, and autism. The study had a non-randomized add-on design consisting of three phases, in which participants were their own controls. In the first phase participants received treatment as usual (TAU) during 6–8 weeks while on the waiting list for EMDR therapy. The second phase consisted of up to 8 sessions EMDR in addition to TAU. The third phase comprised of a follow-up period with the TAU only condition. TAU consisted of the most common treatments for adults with ASD aimed at coping with ASD, psychological distress, and comorbid problems. TAU included pharmacotherapy, psychoeducation, supportive counseling, job

coaching, support with housekeeping, and so-called case management. Results showed a significant reduction of symptoms of post-traumatic stress (measured with the Impact of Event Scale-Revised: $d=1.16$; see Fig. 1), psychological distress (measured with the Brief Symptom Inventory: $d=0.93$; see Fig. 2), and autistic features (Social Responsiveness Scale-Adult version: $d=0.39$; see Fig. 3). Moreover, the participants experienced a significantly lower level of daily life impairment related to the traumatic events following EMDR therapy (thermometer card of the Adapted Anxiety Disorders Inventory Scale for children (ADIS-C) section PTSD: $d=1.81$; see Fig. 4). The positive results were maintained at follow-up. The results suggest EMDR therapy added to TAU to be a feasible and potentially effective treatment for individuals with ASD who suffer from the consequences of exposure to distressing events. It should be noted that the study was based upon a small sample of participants ($n=21$).

The significant reduction of autistic features concerning social motivation and communication following EMDR therapy, and at follow-up, albeit with a small effect size, is remarkable. A possible explanation for this finding might be that the clinical manifestation of autistic symptoms decreases when individuals with ASD experience

Eye Movement Desensitization and Reprocessing (EMDR) Therapy in Children and Adults with Autism, Fig. 1 Mean scores IES-R at four moments in time

Eye Movement Desensitization and Reprocessing (EMDR) Therapy in Children and Adults with Autism, Fig. 2 Mean scores BSI at four moments in time

Eye Movement Desensitization and Reprocessing (EMDR) Therapy in Children and Adults with Autism, Fig. 3 Mean scores SRS-A at four moments in time

less trauma-related stress and psychological distress, such as somatization, depression, and obsessive-compulsive symptoms. Hence, it is conceivable that trauma-related symptoms are a moderator for the severity of ASD symptoms, such that exposure to trauma and other adverse events exacerbate autistic core features like deficits in social-emotional reciprocity (e.g., reduced

sharing of interests, emotions, or affect; Wood and Gadow 2010). Another possible explanation for the observed reduction of autistic features in the study is that symptoms ascribed to phenotypic features of ASD may in fact be symptoms of PTSD, the phenomenon termed *diagnostic overshadowing*. For example, hyperarousal as a consequence of exposure to trauma may be

Eye Movement Desensitization and Reprocessing (EMDR) Therapy in Children and Adults with Autism, Fig. 4 Mean scores ADIS thermometer card at four moments in time

interpreted as an autistic feature similar to hyper-reactivity to sensory stimuli. Also, trauma-related avoidance of social situations can be confused with autistic features similar to problems in social communication. In other words, symptoms of PTSD can be masked by symptoms of autism, therefore symptoms of PTSD, previously seen as features of ASD, might have declined as a result of EMDR therapy.

Future Directions

Clinical Implications

The following practical recommendations based on current knowledge can be made for future clinical practice.

- Awareness of the impact of adverse events and trauma in individuals with ASD is important to prevent undertreatment.
- There is a high prevalence of being bullied in individuals with ASD (Hoover 2015; Maïano et al. 2016). Exposure to bullying is associated with severe psychiatric outcomes in adulthood. Bullying does not comply with the (i.e., A-criterion) definition of trauma in the PTSD section of *DSM-5*. When there is no formal

PTSD-classification, there is an extra risk of undertreatment of the trauma-related symptoms. Disturbing memories of being bullied (e.g., social situations where participants felt excluded and intimidated) can be reprocessed with EMDR therapy.

- Trauma history and associated trauma-related symptoms should be routinely assessed in individuals with ASD who present to clinical services, taking into account the social communication impairments. What is not explicitly asked for often remains undisclosed, because of inability to spontaneously share relevant information. This issue can be addressed by making use of the concrete, visualized, and structured way in which potentially traumatic events and trauma-related symptoms are probed by the Diagnostic Interview Trauma and Stressors-Intellectual Disability (DITS-ID; Mevissen et al. 2016, 2017, 2018, in press), such that also in children and adults with ASD unprocessed memories can be identified. The DITS-ID is the latest DSM-5 based version of the Adapted Anxiety Disorders Inventory Scale for children (ADIS-C) section PTSD. All documents (only in Dutch language) belonging to the DITS are available and can be downloaded for free. See <https://www.accare.nl/childstuddycenter/opleidingen/bijbscholing/dits-lvb/aanvragen-documenten-dits-lvb>.

- Trauma-related symptoms and PTSD in individuals with ASD can be treated successfully with EMDR therapy, taking into account aspects of their specific information processing. The EMDR procedure for children can be used, when the language of the EMDR protocol for adults is too abstract for people with ASD (Dutch version, De Roos et al. 2014). Individuals with ASD seem to need more time to become familiar with the therapist and the procedures and to fill out questionnaires. In case of obstacles when administering EMDR therapy to individuals with ASD, see the link to the following document: *Guidelines and tips for EMDR treatment for Autism Spectrum Disorders* (Special Interest Group EMDR – ASD November 2013, <https://psycho-trauma.nl/wp-content/uploads/2014/01/GuidelinesEMDRASD-1.pdf>). These preliminary recommendations are based on well-established and evidence-based practices for working with this population.
- Based on clinical observations, EMDR therapy seems difficult to perform in individuals with ASD who have problems with activating the traumatic memories because of fear of affects, in combination with severe problems in self- and emotional regulation, a cognitive, rigid, and extremely negative mindset. These individuals are often exposed to prolonged and repeated trauma such as childhood sexual abuse and domestic violence (complex PTSD) and/or are exposed to prolonged and repeated overload and relational mismatches between the needs of the individual and the possibilities of the environment. The iatrogenic effects of inadequate treatments due to delayed diagnostics or inadequate facilities should not be underestimated in these subgroups.
- EMDR embedded in treatment as usual seems appropriate and necessary given the comorbid psychiatric conditions and/or structural problems at home, school, or work in individuals with ASD.

Scientific Implications

Controlled trials with sufficient power to detect differences are greatly needed to confirm the

present findings and to test the hypothesis that EMDR therapy is more effective than treatment as usual in reducing trauma- and stressor-related symptoms. Investigation and experimentation into other evidence-based trauma treatments like cognitive behavioral therapy with a trauma focus (CBT-T), narrative exposure therapy for individuals with ASD, and trauma-related symptoms are strongly recommended. More generally, the issue as to how PTSD and other trauma-related disorders manifest or may be masked by symptoms of ASD is an intriguing one which should be explored in further research.

Eyeblink Reflexes

Lindsey Sterling

Department of Psychiatry, Jane and Terry Semel Institute for Neuroscience and Human Behavior
UCLA, Los Angeles, CA, USA

Synonyms

Corneal reflex; Startle response

Definition

The first and most reliable component of the startle reflex in humans. The blink reflex is an involuntary blinking of the eyelids elicited when the cornea is stimulated by touch, bright light, loud sounds, or other peripheral stimuli. The evolutionary purpose of this involuntary response is believed to be a survival-related function, to protect the eyes from potentially harmful stimuli (i.e., threat). When a stimulus is presented to the cornea of the eye, sensory information is carried to the trigeminal nucleus and relayed to the accessory abducens and abducens motor nuclei, initiating a motor response. The eyeblink consists of a rapid contraction of the orbicularis oculi muscle surrounding the eye; this is the most sensitive component of the blink. Strength of the response can be measured by electromyographic activity (EMG) of the orbicularis muscle during the eyeblink, or blink magnitude. Because EMG is quantifiable, it is the behavioral variable often used in startle response experiments designed to investigate neurological indices of fear and anxiety (i.e., amygdala activation).

Eye-Tracking

Definition

Eye-tracking is a technique in which one or more of a subject's eyes are tracked with the intent of inferring, in a moment-by-moment fashion, what the individual is attending to in his or her visual world.

Historical Background

Eye-tracking has had a long history in psychological research and vision science. Some of the earliest reported work using eye-tracking appeared in the late 1800s and early 1900s, focusing primarily on understanding and optimizing visual processes during reading (e.g., the work of Huey, 1898, 1910). Later work, by Guy Buswell (1935), Alfred Yarbus (1967), and others, would use eye-tracking to study more natural visual scanning processes during the viewing of complex scenes such as those found in paintings or photographs. From these early experiments, it was noted that typical individuals, both young and old, when presented visually with scenes with people, and unless given instructions to the contrary, would spend much of their time looking at the people portrayed. Furthermore, it was noted that given a face to view, subjects would largely attend to the eyes and mouth of the face, despite the fact that these static stimuli never changed. Yarbus noted, in his treatise on eye movements: "The observer's attention is frequently drawn to

elements which do not give important information but which, in his opinion, may do so.” This early work, which advanced the primary of social information processing in natural viewing for typically developing individuals, set the stage for modern investigations of the visual strategies employed by individuals with autism spectrum disorders (ASD).
